Deaths reported 2,541: under five years of age 806; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, diarrheal diseases and fever) 315, acute lung diseases 310, consumption 281, diphtheria and croup 116, diarrheal diseases 56, scarlet fever 41, cerebro-spinal meningitis 28, typhoid fever 25, measles 23, whooping-cough 16, erysipelas 6, small-pox 4.

From cerebro-spinal meningitis Boston 10, New York 5, Somerville 4, Baltimore and Cambridge 2 each, Worcester, Lowell, New Bedford, Newton and Hyde Park 1 each. From typhoid fever Philadelphia 9, New York and Washington 3 each, St. Louis 2, Baltimore, Boston, Cleveland, Fall River, Lynn, Springfield and Fitchburg 1 each. From measles Brooklyn 11, New York 6, Philadelphia, Baltimore and Cincinnati 2 each. From

whooping-cough Philadelphia 5, New York 4, Cincinnati 2, Brooklyn, St. Louis, Washington, Providence and Somerville 1 each. From erysipelas New York 4, St. Louis and Somerville 1 each. From small-pox New York 4.

In the thirty-three greater towns of England and Wales with an estimated population of 10,992,524, for the week ending May 29th, the death-rate was 16.6. Deaths reported 3,492; acute diseases of the respiratory organs (London) 196, whooping-cough 111, measles 97, diphtheria 57, diarrhea 39, scarlet fever 32, fever 19.

The death-rates ranged from 6.9 in Croydon to 28.6 in Salford; Birmingham 17.2, Bradford 15.1, Burnley 22.1, Gateshead 23.2, Hull 14.4, Leeds 18.3, Leicester 14.6, Liverpool 22.0, London 14.9, Manchester 20.6, Newcastle-on-Tyne 17.5, Nottingham 16.1, Oldham 20.0, Portsmouth 12.9, Sheffield 24.0, Sunderland 14.7, West Ham 13.3.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 5, 1897, TO JUNE 11, 1897.

The leave of absence granted CAPTAIN ROBERT R. BALL, assistant surgeon, is extended two months.

RESIGNATIONS AND APPOINTMENTS AT THE CARNEY HOSPITAL.

The following changes have been made in the Staff of the Carney Hospital bearing the date of June 7, 1897:

RESIGNED.—Dr. Myles Standish, ophthalmic surgeon. Dr. S. J. Mixer, surgeon. Dr. G. A. Webster, assistant aural department.

APPOINTED.—Dr. Myles Standish, consulting ophthalmic surgeon. Dr. Henry W. Kilbourn, ophthalmic surgeon. Dr. William J. Daly, assistant ophthalmic surgeon. Dr. James G. Mumford, surgeon. Dr. George W. W. Brewster, surgeon to out-patients.

RECENT DEATHS.

FREDERIC JOSEPH MCNULTY, M.D., M.M.S.S., died in Roxbury, June 13, 1897, aged sixty-two years.

JAMES GREIG SMITH, M.A., M.B., C.M. (Aber.), F.R.S. (Edin.), the well-known surgeon of Bristol, Eng., died recently of pneumonia. In the department of surgery, namely, abdominal operations, to which he mainly devoted himself, his successes were great, and he was recognized as one of the authorities upon the subject. His book upon "Abdominal Surgery," now in its fifth edition, is one of the best-known treatises of the kind, and has attained to the position of a classic. He received his medical education at the University of Aberdeen, and was surgeon to Bristol Royal Infirmary, and professor of surgery in University College, Bristol, at the time of his death. At the annual meeting of the British Medical Association at Bristol, in 1894, he delivered the address on surgery.

BOOKS AND PAMPHLETS RECEIVED.

Transactions of the New York State Medical Association for the year 1896. Volume XIII. Edited for the Association by E. D. Ferguson, M.D., of Rensselaer County. New York City: Published by the Association.

Reference Book of Practical Therapeutics. By various authors. Edited by Frank P. Foster, M.D., Editor of the *New York Medical Journal* and of "Foster's Encyclopedic Medical Dictionary." In two volumes. Volume II. New York: D. Appleton & Co. 1897.

A New Classification of the Motor Anomalies of the Eye based upon Physiological Principles, together with their Symptoms, Diagnosis and Treatment. The Prize Essay of the Alumni Association of the College of Physicians and Surgeons, New York, for 1896. By Alexander Duane, M.D., Assistant Surgeon to the Ophthalmic and Aural Institute, New York. New York: J. H. Vail & Co. 1897.

Hysteria and Certain Allied Conditions, their Nature and Treatment, with Special Reference to the Application of the Rest Cure, Massage, Electro-therapy, Hypnotism, etc. By George J. Preston, M.D., Professor of Diseases of the Nervous System, College of Physicians and Surgeons, Baltimore; Visiting Physician to the City Hospital; Member of the American Neurological Association, etc. Illustrated. Philadelphia: P. Blakiston, Son & Co. 1897.

The Liver of Dyspeptics, and particularly the Cirrhosis produced by Auto-Intoxication of Gastro-Intestinal Origin. (Clinical, Anatomic-pathological, Pathogenic and Experimental Study.) By Dr. Emile Brix, Interne Larriat des Hôpitaux de Paris (Médaille d'or, Concours de 1883; Médaille d'or des Epidémies, Cholera, 1884). Authorized translation from the latest French edition by Paul Richard Brown, M.D., Major and Surgeon, U. S. Army. New York and London: G. P. Putnam's Sons. 1897.

Address.

SPECIALISM, THE LABORATORY, AND PRACTICAL MEDICINE.¹

BY F. C. SHATTUCK, M.D., BOSTON,
Jackson Professor Clinical Medicine in the Harvard Medical School.

IN 1891 Dr. Weir Mitchell chose as the theme for his Presidential Address at the Congress of American Physicians and Surgeons, "The Early History of Instrumental Precision in Medicine." Most of you, doubtless, are familiar with the address and recall the wise remarks and suggestions which preface and are scattered through the story of the evolution of the thermometer in medicine. When the most flattering invitation of your officers reached me to address you to-day, I first accepted, and then cast about for a subject; and although neither the mind nor the hand of the master are mine, I thought I could take a suggestion from him, and try to bring before you some considerations which are in the minds of all of us to-day on subjects of great practical importance, subjects which are the direct outgrowth of the rapid development of instrumental and scientific methods in medicine, and which bid fair to revolutionize its practice.

You remember Gerard Dow's picture of the Doctor in his delightfully comfortable fur-trimmed robe holding the flask of his patient's urine up to the light. What would he think, or make out, of the report of an analysis of a twenty-four-hour urine coming from one of our modern laboratories? What would he do with the stethoscope, the ophthalmoscope, the laryngoscope and all the other 'scopes which bring into actual sight more or less hidden parts of the human body? He did wash out the stomachs of his patients, though somewhat indiscriminately as well as crudely, but he would be puzzled to make out or draw any inferences from an analysis of the gastric contents after a test-meal. If ovariectomy was characterized as murder within fifty years, what would he have thought of opening the abdomen simply to make a diagnosis, or of trephining for headache? How would a technical report of the electrical reactions in health and disease strike him? Would he accuse of witchcraft the person who showed him one of his fractures under the Röntgen rays? All these and many similar means are laid under contribution by the clinician in his strivings toward exactness in diagnosis and toward a therapy somewhat more than empirical.

That wise man, Dr. James Jackson, of Boston, is said to have remarked, perhaps fifty years ago, that there was at that time more absolutely known about medicine and its practice than the mind of any one man could grasp. How many minds are required to-day?

Specialism is a natural and necessary result of the growth of accurate knowledge, inseparably connected with the multiplication and perfection of instruments of precision. It has its drawbacks, absurdities even. We have an Association of *Official Surgeons* in this country. A few years ago a recent graduate and ex-hospital interne asked me, apparently seriously, to give him the name of a specialist in rheumatism. We can afford to laugh at these things. We can assent to the truth contained in the remark made to me by a shrewd and broad-minded country doctor, as

he called himself: "It takes an almighty bright man to be a specialist." We all feel at times that most of our energies are spent in telling our patients what specialist to consult; but at the same time we fully recognize the great debt which special workers are rolling up on the human race. The specialist can match the stories of the general practitioner who finds that some whom he supposed to be his patients are receiving local when it is general treatment which is required, by instances of the neglect of a local mischief which is really at the root of the ill health. The specialist and generalist, if you will permit me to coin a word, are complementary and time may safely be trusted to perfect their relations to one another. This time adjustment has already taken place in great measure with regard to the older specialties. These are nearly all clinical, *stricto nomine*. The ophthalmologist, otologist, dermatologist is still a practising physician, and is none the worse specialist if in his early years he had, even if he did not enjoy, a general experience.

But within a few years a marked change has come over the relation of pathology to practice. Until recently the pathologist had but little to do with the living. He carefully sought for the cause of death, studied the ravages of disease, and immensely strengthened the hands of the clinician whether the latter was right or wrong. But his work was still comparable, as Dr. Holmes wittily put it, to the inspection of the fireworks the morning after the Fourth of July. He saw the result; he saw many of the steps by which the result was brought about; but the underlying cause eluded him. Consequently pure pathologists were in this practical country few. But a change was wrought by the demonstration of the close connection between many diseases and minute living organisms; by the immense aid furnished to the study of these creatures by their experimental growth on solid media; by the application of stains; and by the improvement of the microscope. Bacteriology has thus immensely clarified pathology, enlarged its scope, and brought it into closer connection with clinical work than it had ever occupied before. But the enlargement of the pathological field involves, as it seems to me, centrifugal as well as centripetal forces. It appears to be almost inevitable that laboratory specialism must be added to clinical specialism and must enlist a considerable body of men in its ranks. The day is not far distant when every large hospital must have its pathologicat laboratory as much as its operating-room, with a trained and well-paid head, busied as much with the solution of problems arising in the living as with the determination of the cause of death. At the same time that the pathologist comes into closer relation with the living in one way than he has done before, in another he becomes more widely separated. There is ample opportunity for the use of all his time and all his faculties in one branch of medicine. He thus becomes a specialist; and a specialist he is likely to remain as, doubtless on the whole for good, the practice of pathology will be less frequently a mere stepping-stone to the practice of medicine in the future than it has been in the past.

In thus trying to forecast the future I think I realize that we are in a transition state; but when was the world not in a transition state? The germ of progress has spread even into Africa. The bacteriological side of pathology has all been developed since

¹ An address delivered before the Rhode Island Medical Society at its Annual Meeting, June 3, 1897.

those of us who are in middle life finished our school education, and we are now both too old and too busy to learn and carry out ourselves many of the practical details which the best care of our patients demands. For these we must rely on others, whom in our turn we help by supplying the material for investigation and farther discovery, as well as by adding the reagent of practical experience to the products of laboratory research. But it is my belief that our successors will be less rather than more independent of the laboratory specialist than even we are. Physiological and pathological chemistry have scarcely chipped out of the egg. Better knowledge of bacterial products bids fair to influence therapeutics as profoundly as that of bacteria has influenced pathology.

I have made the highly original remarks that specialism has its drawbacks, that we are in a transition period, and that time—which means fuller knowledge—will reconcile the seeming opposition between clinical and pathological facts with which we sometimes have to contend to-day. Allow me briefly to touch on some of the difficulties which we have to meet, armed with such a measure of knowledge and common-sense as we are at present seized and possessed of. We have reason to believe that diphtheria is a bacillary disease; nay more, that we are acquainted with and can recognize its bacillus, which we call the “Klebs-Löffler”; that the disease is communicable by the transference of the bacillus more or less directly from one person to another. Logic would seem to demand that diphtheria should cease were the bacillus as extinct as the great auk, also that meanwhile every person harboring its bacillus in the live state is in danger himself and a menace to others. At first the discovery of the Klebs-Löffler bacillus seemed an unmixed blessing, as it appeared to make it possible within twenty-four hours at most to differentiate diphtheria absolutely from all other forms of sore throat. And we were painfully conscious that the naked eye alone in some cases was not competent to enable us to make this differentiation, however important it might be. A mild and unrecognized case might spread fatal disease, though never causing any anxiety itself. But we soon found that it was not all plain sailing. In the first place, the throats of patients who have been through the disease and are in every other respect perfectly well and safe to mix with the world are found to harbor the Klebs-Löffler bacillus for days and weeks. Secondly, it is found that inmates of a general hospital ward, free from signs or symptoms of diphtheria or any other disease localizing itself in the throat, not infrequently have in their fauces organisms which answer to every criterion of the Klebs-Löffler bacillus at present known. Thirdly, of all children admitted to the Children’s Hospital in Boston from December, 1895 to April, 1897, 7.9 per cent. had the Klebs-Löffler bacillus in the throat, though none of them had any other evidence of diphtheria. These facts in conjunction seem to me to show one of two things: either that the Klebs-Löffler bacillus is innocuous to its host and apparently to others under certain conditions, or else that there is some other organism which closely resembles it—so closely that at present we cannot tell them apart. If the former is true, we must ascertain what the conditions are that determine virulency or non-virulency: if the latter, the sheep must be separated from the goats.

Still another difficulty may be mentioned. We hoped at first that twenty-four hours would remove all doubt from a doubtful case and shorten our suspense. So it does if the culture is positive. But a single negative culture offers a double possibility of error—lack of skill on the part of the practitioner and a failure of technique or observation on the part of the bacteriologist. And if we must wait for two or three cultures before we reach a decision, we and our patients are not much better off than in ante-bacillary days.

For the present it seems to me that we should not be guided purely by laboratory considerations in deciding when our convalescent diphtherics may be turned loose with safety. The court of final appeal must always be the general practitioner, whose business it is to adjust scientific knowledge to the complicated conditions of human life.

Modern research, again, has shown us that tuberculosis is spread mainly from the sputum of consumptives, though the milk of diseased cattle may be apparently partly responsible. It is probably wise economy, as well as logical, to detect and destroy tuberculous cattle. Not even the sentimentalists, as far as I know, have protested against this course, though doubtless, had the animals a choice, they would prefer to live.

Nobody has as yet proposed in the interest of preventive medicine that we should test the whole community with tuberculin, like a herd of cattle, and kill the disease. But what seems to me mental astigmatism has incited or aided attempts at legislation, the wisdom and necessity for which the facts of practical observation within the reach of all strongly contravene. This winter a bill was introduced into the Legislature of the State of Massachusetts, which I do not hesitate to characterize as monstrous. If passed, it would have closed the doors of every private hospital, home or institution against consumptives, unless such hospitals, etc., received a license by the *unanimous*—mark the word—vote of the aldermen or selectmen with the approval of the mayor and board of health. Section 4 provided that, “any individual person, or any official, trustee, director, agent or servant of a corporation, who violates, or aids or abets in violating, any of the provisions of this act, shall be punished by imprisonment in the jail or house of correction not exceeding two years.” Consumption in this bill is classed with small-pox, diphtheria, membranous croup, measles, scarlet fever, typhus fever, yellow fever and cholera. This bill received such feeble professional support and was so manifestly absurd, that after several hearings, the Committee on Public Health reported in favor of a bill from which the worst features of the original bill were removed. Public and private institutions were still to remain on a different footing; existing institutions were not to be meddled with; but extensions to them, or the establishment of new institutions, would require licenses granted by three-fourths of the aldermen, or a majority of the selectmen, as well as the approval of the mayor and board of health, with provisions for the revoking of such licenses. A fine of \$100 to \$500 a month was substituted for imprisonment in jail as a penalty for the violation of the provisions in the act. I rejoice to say that even in this milder form the bill failed by a considerable majority to receive the approval of the House of Representatives. I said before the Committee, and I repeat here, that legislation does not seem to me to be called

for in this direction at present. Boards of health have the power now to regulate or even close institutions which are a menace to the public health. It is an easy matter to frame, and should not be difficult to enforce, regulations which make such institutions practically safe to the surrounding neighborhood. As far as danger of infection goes, I should have no anxiety for my family or myself were a properly managed consumptive hospital next door to me, though I might not consider its presence as indicative that real estate in my neighborhood was rising in value.

The early and accurate diagnosis of consumption is greatly facilitated by sputum examination. All classes of the community must be taught that the sputum is dangerous, and how it is to be robbed of danger. We are a spitting people, but we are quick-witted and can be taught to spit with discretion. It would be well to

ployee of any kind has been infected, as far as is known. The same gracious lady who started the hospital is still resident and at its head, and assures me that no person admitted for other disease has acquired consumption to her knowledge. Six others have been in residence from eleven to thirty-three years, among them a ward-maid for thirty-one years, and a night-nurse for seventeen years. The whole number of patients admitted from January 1, 1861, to January 1, 1897, is 4,254. Much labor would be required to determine exactly how many of them were cases of phthisis; but I have been able to get the exact figures for the years 1888-1891, both inclusive. Of 1,043 admissions during this period, no special precautions being taken as regards the sputum, 297 were consumptive. Many of them stayed for months. Cleanliness, free ventilation and sunlight have always been consid-

provide more institutions for the care of those consumptives whose circumstances do not permit proper care at home. But it does not seem necessary, in accordance with recommendations lately made, that such institutions should be rigorously confined to more or less remote and inaccessible hilltops. The oft-quoted experience of the great Brompton Hospital for Consumptives in London—experience gathered, it should always be remembered, in pre-bacillary days when no special precautions were taken as to the sputum—proves to any unbiased mind that even confined spaces where consumptives are closely aggregated, live, move and have their being, are practically innocuous to the attendants and employees. This experience is supplemented, though in a smaller way, by that of the House of the Good Samaritan, of Boston, a small hospital of twenty-eight beds, nearly one-third of which are occupied by consumptives, the rest by patients with diseases of various kinds too chronic in character for the larger hospitals. For many years I made daily visits through six months annually, and am now consulting physician to this institution. In the thirty-six years since that hospital was opened one nurse has contracted consumption. No other attendant or em-

ployed of prime importance. Trudeau's experience at Saranac, and that at Falkenstein and Görbersdorf in Germany, are corroborative. The vital statistics of the State of Massachusetts show a constantly declining death-rate from consumption, in spite of the growth of cities and an increase in the density of the tenement-house population. In 1853 the rate was 42.7 per 10,000; in 1895 it was 21.8 per 10,000 living.

The chart² shows that this diminution in consumptive mortality is practically continuous, and there is no reason to believe that it materially differs from the facts. It will be noted that the diminution in the last is no greater than in previous decades. Probably proper precautions as to sputum have not as yet been widely enough observed to count for much in the mortality returns. It is certainly reasonable to hope that we shall soon begin to see the good effects of the destruction of the seed. The results up to the present time can be fairly attributed only to attention to the soil—that is, the tissues of the body—which is becoming constantly less favorable to tubercular growth through a higher average of general hygiene, better food and houses, better ventilation and plumbing, more

² Vital Statistics of Massachusetts, 1893, with 1894 and 1895 added.

seusible clothing, more active exercise and outdoor life. England has no quarantine, believing it to be more practical to keep clean than to exclude the germ.

Laboratory evidence is of inestimable value already, although its present services are probably only an earnest of what is to come in the future; but it is not and never will be *all* the evidence. Truescience takes cognizance of all the facts, clinical as well as pathological, chemical, physiological or what you will; and when the deductions from all the facts are applied to the complicated conditions of modern civilization with a view to action, that highest wisdom which may be called uncommon sense must be exercised if the best results are to be obtained in the prevention and limitation of disease.

There may be no pathological difference between two samples of pus containing gonococci, one derived from the genital tract of a man about town, the other from that of a little girl; but it does not follow that the disease was contracted in the same manner in the two cases. Indeed, the vulvo-vaginal catarrhs of little girls, even with gonococci, are almost always morally innocent. We can go farther, and say that no pathogenic germ is *the* cause of a given disease; it is only a cause, or one of the causes, or there would be no such thing as immunity, means for the cultivation and artificial production of which must and will be most carefully studied. Why are the colon bacillus and the pneumococcus usually innocuous in the colon and in the mouth, while so virulent there or elsewhere in the same person under other conditions? Nay, we must go farther still, and never forget the teachings of history which show that the fact of yesterday may be shown to be no fact to-day or to-morrow. Finite minds are dealing with infinitely complex conditions, and the only wonder is that true progress is as rapid as it is. I earnestly hope that no one will misunderstand me as in word or thought slighting the laboratory specialist or his work. As actions speak louder than words, I may perhaps be permitted to mention that, when about a year ago I had the opportunity to influence the direction which a large gift to medicine should take, I urged the endowment of a chair of Comparative Pathology. Not that clinical teaching is amply provided for now and for all time. But the wisdom of most hospital trustees in encouraging clinical teaching in the institutions under their charge leaves us free for the present to promote the establishment of the more purely scientific laboratories which must be maintained, and presided over by specialists. No medical school can ever attain the highest ideals without a commanding voice in the selection of the staff of a good-sized general hospital, and in the regulation of the terms of service. The functions of a laboratory are threefold: research, integral parts of ordinary medical education, and indispensable aids of the practitioner of medicine and surgery, general or special, who would do full justice to his patients, the community and himself. We need instruments of precision, laboratories to put them in, and highly trained men to make the plant fruitful, remembering always that behind all his works is man himself.

An immense strain has come upon medical schools of late years. The didactic lecture to large classes gradually yields to or is supplemented more and more by clinical teaching in small divisions; and this means great multiplication of teachers. But this strain is as

nothing to that of the establishment and maintenance of laboratories. The salary of the clinical teacher is incidental. To be a good clinical teacher he must keep in touch with disease outside as well as inside the hospital. But the head of a laboratory, and also some at least of his subordinates, must be independent of practice. Fortunately for the world there are men of the first ability who are willing to live frugally for the kingdom of science's sake. "There is one God, and Science is the Knowledge of Him," is the closing sentence in the "Analytic Mechanics" by the late Prof. Benjamin Peirce. But we must not demand too much of these men or the supply will fail.

One after another we see the leading medical schools of this country ceasing to be proprietary and getting under the wing of a university. Only there is dignity — life, even — to be preserved. The fees of students alone cannot support a modern medical school, and gifts and endowments will not flow to the proprietary school. The spirit of our institutions commands that, while the State must provide for the lower, the higher education is to be left to private munificence. The experience of the past justifies confidence in the future; but the medical profession must not remain entirely passive in the matter. There are many persons in this country who recognize their trusteeship of wealth and are anxious to benefit the community. Some of them share the feelings of a rich Bostonian who left a sum to be divided by his trustees among such charitable institutions as did not make two paupers where there was one before. Some do not know exactly what form their generosity should take, and seek advice or follow casual suggestion. But few understand what preventive medicine and the study of the causes of disease do for mankind; and yet it seems to me that any person with ordinary apprehension must understand the facts if put before him. How can a person more benefit his kind, with less danger of immediate or remote ill consequences, than by promoting the possibility of such studies? How can he be so sure that he is building for all time as in laying foundations for research into the causes, prevention and treatment of diseases? For disease must be coeval with man's mortality. The endowment of theological study is manifold that of medical study, although the number of theological students is far less and the necessary expenses of education are comparatively insignificant. The possible benefits to be conferred on men by astronomical would seem to be small as compared with those to be attained by medical research. And yet the former appears to excite more enthusiasm, relatively at least, among donors than the latter.

The medical profession — individually in its relation with patients, more or less collectively through its associations, geographical or other — has many opportunities for influencing gifts and bequests. Do we exercise this influence as much as we ought to? I am tempted to ask myself whether we may not show an excess of professional delicacy — leaning over backwards as the modern phrase is — with regard to our patients. It is one thing to ask for ourselves, another to point out opportunities for usefulness to descendants, neighbors and friends, to the whole human race, nay to all living beings; for human and animal pathology are becoming more and more closely intertwined.

The higher we mount the more extended is the view. Through the harmonious co-operation of specialists, each in his special line, and of general practitioners,

all mutually interdependent, our imagination probably cannot outstrip the realities of the future progress of the profession to which it is our pride to belong and which we love so well.

I thank you, Fellows of the Rhode Island Medical Society, for your kind attention, and you, Mr. President, for this great privilege which you have accorded me.

RELATION OF NEURASTHENIC SYMPTOMS TO THE GENERAL NUTRITION.¹

BY ROBERT T. EDES, M.D.

(Concluded from No. 24, p. 592.)

THE nerve centres have a nutrition of their own, and receive according to their own requirements a larger or smaller share of the nutriment offered by the general circulation. It cannot, of course, be perfect unless a sufficient amount of appropriate nutriment be carried to them; but it is evident from the state of the blood in many persons who have nervous systems in good working order that quite a wide limit is permissible in the concentration of the fluid which bears it; that is, that the nervous substance can select and utilize from a solution bearing the appropriate pabulum in quite widely varying degrees of dilution, enough to carry on its ordinary functions without exhaustion. I am not sure, though this is not easy to demonstrate by figures, that this does not apply equally well to the ability to store a reserve force for extraordinary demands.

The rapidity of the circulation, as influenced by cardiac vigor and vascular tension, may be able to compensate for deficiency in composition, since the same amount of blood, if it contains a little smaller percentage of oxygen and peptone may, by making the circuit more rapidly, convey in a given time the same amount as a richer fluid in more sluggish motion.

On the other hand, a nerve centre which is incapacitated from selecting and assimilating its appropriate pabulum cannot be forced to do so. We can force food into the stomach and usually fat under the skin, and to a certain extent hemoglobin into the blood; but it is by no means easy to force potential energy into the neuron and the muscle fibre, unless there exist upon the other side a harmoniously acting stimulus.

The restitution of the normal structure of the exhausted neuron is a process of growth, demanding time, rest, and also that unknown element which makes all growth to a great extent qualitatively independent of its surroundings and not a mere process of osmosis dependent upon a balance of pressures or relative concentration of salts.

When we get beyond mere exhaustion and have to deal, not with a temporary deficiency of force, but with acquired abnormalities in its manifestation, or, further still, with congenital peculiarities, varying in each case from the mild hypochondriasis of the chronic invalid to the fixed idea of the delusional insane or

the paranoiac, the therapeutic value of nutrition alone decreases in proportional importance, although, of course, it is still the basis upon which other and more specific treatment must rest.

Cultivation in plants and education in animals can in a single generation increase the useful output up to a certain limit, and in many generations, aided by selection, can greatly improve the quality of the product; but no amount of fertilizer can make the stunted pine of the pasture, gnawed and trampled on by cattle and hacked by boys, grow into the stately column of the forest, or the cabbage to secrete cinchona alkaloids or exhale the perfume of the rose. No amount of oats will make the draught-horse into a racer, and neither beef-steak nor "nerve foods" will make the chronic neurasthenic capable of easy and efficient work. What removal of special obstacles and the adjustment of the work to be done to the best nutrition possible in each individual case, may do in securing the maximum efficiency and comfort in productive labor of the nervous system is another matter entirely.

If there were any way of measuring the potential energy of the neuron, and especially its storage capacity, without exhausting it, we could then directly and accurately get at what we now try to do by inference, and could study the phenomenon of fatigue side by side with the means of repairing it. But trying the experiment of exhaustion, however interesting it might be and instructive as regards theory, would be therapeutically hazardous as regards the individual patient, emptying the reservoir we are trying slowly and laboriously to fill in order to find out exactly how much it holds.

A study of this class of cases in the psychological laboratory, and especially by the continuous method of Kräpelin and his school, could hardly fail to give results not only of interest but of great value, but would require to be made with great care. I have found in a very few instances that the effort of attention necessary to a trial of simple reaction-time was felt as a serious strain, and I think that many of us would recoil from frequently repeating such an experiment as trying to commit to memory in the shortest possible time a set of nonsense syllables while some one was reading an interesting book within hearing.

Many papers have been written about the nervous symptoms of "lithemia" or uric acid in the blood, and indeed this condition figures among the many comprehensive theories of neurasthenia. But the literature is out of all proportion to the amount of proof that any relation of causation exists between them, or even that uric acid exists in excess at all in the blood in cases marked by neurasthenic symptoms. This acid was found by Garrod many years ago in cases of gout, by an approximate method; but exact quantitative methods for its measurement in the blood are fitted only for the laboratory and not for ordinary clinical work, demanding quantities of blood not afforded by modern therapeutics. These methods have found it in cases other than gout: as in several forms of anemia, leucocythemia, as well as in some diseases causing dyspnea. Neither of them, so far as I am aware, has detected it in neurasthenia. The whole doctrine indeed rests on plenty of testimony but very little evidence.

A quantity of uric acid in the renal excretion, varying in either direction from an average or assumed normal, either in twenty-four hours' amount or in proportion to

¹ Read to the Association of American Physicians, Washington, D. C., May 6, 1897.

urea, can, of course, be readily demonstrated in these as in other cases; but it has been chiefly since the laborious observations and ingenious speculations of Haig that attention has been strongly directed toward uric acid as the special poison causing many nervous symptoms. Before him it did not have even the indirect support of quantitative urinary analysis, but rested merely upon the presence, in connection with certain symptoms, of an increased deposit of urates, a phenomenon which, as is well known, depends upon many other conditions than an increased amount in the circulation or even an increased elimination. Hence the principal objection to the word lithemia as a name for a group of symptoms of a more or less neurotic character and probably dyspeptic origin, is that it assumes a definiteness of knowledge which does not exist. If, as seems highly probable, these symptoms are really of toxic origin, it is by no means proved that uric acid is the only or even the usual poison.

Whether this poison is to be found within the uric-acid group, as is supposed by Rachford, or whether it is a single or more probably a group of products of intestinal decomposition, further examinations must show. The tenacity with which the urinary coloring matters cling to uric acid through all the vicissitudes of chemical manipulation may suggest that here perhaps is some explanation of the bad repute of the latter, and that the apparent accessory may be the real principal.

The recent theories of Haig, based upon a large number of careful observations, have been woven into a doctrine so complicated and involving so many suppositions which cannot be either proved or disproved, that it is almost impossible to criticise them fairly without going exactly over his ground and making continuous observations every few hours for many days. His fundamental assumption, that the rate of formation of uric acid to urea is a nearly constant one of 1 to 35, I have found very little to confirm, though I have not followed any one person long enough to justify me in claiming to have established the habit and rate of a lifetime. Among about 100 persons examined once or more, I have found this ratio, or very near it, in twenty persons; and in somewhat more than 200 examinations about 31 times. More than, or equalling 1 in 55, the proportion suggested by Herter as more usual, I have found about 90 times in forty-five persons including the above.

In going over the records of these cases in the endeavor to find some correspondence approaching constancy between either an excess or diminution of uric-acid excretion and the severity of the other nervous symptoms, or of any special symptoms, the result is far from satisfactory; and this is true both as to the total twenty-four hours' output and the proportion to urea.

The nearest to such a correspondence is to be found in some cases of severe headache where, by assuming as a normal maximum the fraction one fifty-fifth, there appears to be an excess of uric acid excreted. But the number of such cases is not large, and with them are others where this proportion is to be found without the headache, and, on the other hand, the headache with a proportion of uric acid considerably below this; so that it is forcing matters very much to assume a relation of causation in the remainder. It is, of course, true that, in order to controvert the views of Haig, his methods should have been strictly followed and exam-

inations made at more frequent intervals than was done in any case.

Hence there is nothing in these observations to disprove the possibility of a paroxysmal uric-acid headache, but they certainly seem to show that a constant neurasthenic headache is not of this character.

Miss P., in seven times out of ten examinations, had a proportion of uric acid in excess of one fifty-fifth, and twice of one-thirtieth or more. The quantities of urine and of urea were about normal, and the total uric acid usually above 500 mgr. She complained of constant headache; but her general appearance, her gain in weight and her subsequent history lead me to doubt very much the severity, if not the existence, of extreme suffering.

Miss D., with a quantity usually below 1,500, and urea below 20, had a proportion of uric acid more than one forty-fifth, five times in five observations. She had a nearly constant headache, and has already been mentioned as having steadily lost weight, and being now in a condition of very slow and tedious recovery.

Miss G. used to have attacks of severe hemicrania, beginning with zigzags before one eye, succeeded by headache upon the opposite side. She gained weight, and improved. Toward the end of her stay she lost weight a little, but continued to improve; and a year or two later she called to see me, and said she had been constantly better. During the time that she was losing a part of the weight that she had gained, the following observation was made (see page 619).

Two others follow, in which the excretion of uric acid does not have any special relation to the symptoms. In one of these (Miss T.) the remarks taken from the record do not correctly express the constancy of the headache, which was practically continuous, hardly intermitting for more than an hour or two at once. It might seem that here, with a constant proportion of the acid beyond that which has been found more nearly the usual with us than Dr. Haig's one thirty-fifth, that is, one-fiftieth or thereabouts, we have a strong case in favor of his theory as modified to suit our conditions. In reality, however, it is hardly so at all. Although these observations were made chiefly within two months, the time during which the patient was under treatment—never able to take a full meat-diet, and having not infrequent gastric attacks, having taken eliminatives, with a fair elimination of water all the time and a quantity of urea quite as large as could be expected with her moderate diet—was much longer. The continuance of the headache up to the present time, then, if caused by a constant flow of uric acid, would argue a previous accumulation of great magnitude. Her headache has been relieved neither by acids nor alkalies. The existence of such a fund, although it cannot be absolutely disproved, is certainly in the highest degree improbable. There were no indications other than have been mentioned of a gouty diathesis; and in a tall, thin, pale woman, with a blood-color of below 50, losing weight, whose previous history was that of a country school-mistress, supporting herself and her father, we certainly have conditions as little favorable for acquiring lithemia as can well be imagined.

Dr. Haig's theories are provided with so many ingenious adjustments that it is almost useless to deny their applicability to any case when the attempt is made by willing hands. The assumption of a reserve of unknown quantities of uric acid accumulated under

the most adverse circumstances and stored where it is inaccessible to chemistry and betrays itself by no symptoms, places the advocate of the theory in a position practically unassailable.

In a paper by Dr. Gertrude Van Pelt,² there are a number of cases reported with nervous symptoms supposed to be connected with uric acid. In one of these, a chronic invalid "who had been all over the world in search of health and had had all kinds of treatment," the nervous symptoms included neuralgia, headache, insomnia, and dysmenorrhea. Her urine was always very scanty, and often loaded with urates. Now, if

such symptoms as these are due to uric acid in the circulation, it seems as if this patient must have been getting rid of it for many years instead of accumulating, for Haig takes the quantity in the urine as an index of the quantity in the blood. It is not a very far-fetched supposition either, that such a patient had drunk no inconsiderable amounts of alkaline mineral waters in her day, which could hardly have allowed the process of accumulation to date back to childhood. It thus becomes very interesting to know how, after taking salicylate of sodium for two and a half months, she could have had a total twenty-four hours' amount of uric acid very considerably in excess of the normal, and a proportion to urea even more so. The exact figures were .90 and one-eleventh. The former of these is larger than the average for strong and healthy persons on a full diet; more than I found in my own case; with a single exception, more than given by Luff³ among 50 determinations in a healthy man on a mixed diet; and more than I have ever found in about 100 persons, many of whom had symptoms not unlike the case described.

The last observation consists in an experiment upon myself, to determine whether the passage of uric acid through my circulation would produce a headache. It will be seen at once that in this point of view it was a

² Boston Medical and Surgical Journal, vol. cxxxiv, p. 129.

³ London Lancet, 1897, p. 947.

failure, since the acid, either solid in the stomach or in the form of urate of potassium in the rectum, must have failed of absorption. It is introduced, however, for purposes of comparison, and with the remark that neither on the days when the total was less than usual (22d), or high (14th and 23d), or when the proportion was at its lowest (22d), or highest (14th, 20th, 21st), or on any other day was there any headache.

The neurasthenic condition is quite as likely to be connected with an amount of uric-acid elimination below the average as up to it, and much more so than with an excess. This, however, is connected not with any storage or special condition of this substance, but is simply a part of a general sluggishness or inhibition of metamorphosis, as shown by diminution in the total amount of urine and of urea.

The phosphates have not been examined often enough to give any important indication, and the same must be said with reference to indican considered as an indicator of intestinal putrefaction.

SPRAINS AND THEIR TREATMENT.¹

BY DOUGLAS GRAHAM, M.D., BOSTON.

(Concluded from No. 24, p. 594.)

TREATMENT OF SPRAINS.

AN eminent surgeon once remarked to me, "What you do, doctor, with your massage and movements, is to cure the patients of the results of our treatment." The customary treatment of sprains and its results are well known—absolute rest in a fixed dressing, resulting often in recovery, but too frequently in stiff, weak and irritable joints. Sometimes these joints are deliberately sprained over again by the surgeon, with a view to loosening adhesions and overcoming the stiffness. But, unfortunately, this plan may cause the adhesions to reform stronger than ever.

A form of treatment that is no doubt well adapted for sprains of slight or moderate severity of the outer aspect of the ankle has recently been revived by Dr. V. P. Gibney, of New York. It is strapping with strips of rubber plaster alternately at right angles to each other over the outer and lower third of the leg, ankle and foot. Elevation of the foot over night or for a few hours, and immediate massage, are advised as good preliminary measures before applying the plaster. This treatment is said to involve no loss of time, requires no crutches, and not to be attended with any ultimate impairment of motion. This plan of strapping sprained ankles with adhesive plaster was used with brilliant success by Dr. Wharton P. Hood's father on himself fifty years ago. It is well to call attention to these matters occasionally.

I wish now to propose a better, simpler and quicker way of carrying out this same plan of treatment, as it is applicable at one and the same time to all mild sprains of foot and ankle. If the patient is wearing a well-fitting boot at the time of spraining foot or ankle, let him keep it on and walk about moderately. If the boot is not quickly snug by reason of the swelling, it should be laced tighter. I have twice walked off a mild sprain in this way myself. The pressure of the leather and the motion of walking give a sort of auto-

matic massage. And when we think of it, this is not so very wonderful after all, for it is safe and salutary to allow motion in sprains that does not cause pain. It is unnatural motion that has caused the injury, and even after this, natural motion can often be immediately indulged in to a greater extent than either physician or patient take the trouble to find out.

A plan of treatment that seems to be well suited to sprains of all degrees of severity, and which can be used with or without fixed dressings and bandages, according to the indications, is massage properly applied. Massage should not be begun immediately over a recently injured joint; neither should passive nor active motion be encouraged in spite of pain caused thereby, whatever others may say to the contrary. After a recent injury, to my mind, pain is the cry of nature for rest to allow repair. And it is quite possible in sprain, and even in fractures without displacements, to keep the injured parts at rest while the surrounding tissues are preserved in health and activity, the circulation kept active and absorption hastened by means of massage.

A snug bandage is usually sufficient to afford rest and support, and to press the swelling out in the intervals between the massages. But if the bandage does not give sufficient support, then an easily removable splint or plaster may be applied. Joints tender and swollen, that do not admit of massage being applied directly upon them, can be approached by commencing on the healthy tissues some distance above them and nearer to the trunk, by gentle stroking or effleurage in the direction of the returning currents of lymph and blood, and gradually proceeding downwards. The healthy tissues beyond the seat of the injury should also be similarly treated, as the circulation is hindered in getting to and from them by reason of the swelling. Besides the soothing effect of this, which enables one to gradually encroach upon painful parts, the returning currents are pushed along more rapidly, making room for exudations to be carried off. For this purpose each hand should make alternate strokes, using the greatest possible extent of the palmar surface whilst the limb is in a comfortable position.

After working a few minutes in this manner, deep manipulation, or massage properly so-called, may be brought into play, beginning as before above the painful joint by adapting the greatest possible extent of hand and fingers, one hand contracting and making the greatest push upwards as the other relaxes while gradually approaching the objective point. The effect of this is agreeably benumbing or analgesic, lessening pain without decreasing ordinary sensations, besides pushing along the deeper circulation more vigorously. The parts beyond the sprain should be treated likewise. By alternately stroking and kneading in this manner we can soon make gentle, firm pressure over the but recently painful and swollen joint. If sufficient tact be used this pressure may not hurt, but be positively agreeable; and very soon it can have motion added to it, thus constituting massage by which the effusion and exudation are spread over greater surfaces and brought into more points of contact with veins and lymphatics, absorption by which is materially aided by the pressure of massage.

It should not be forgotten that when a light touch is disagreeable, firm pressure often affords relief, so that the whole hand is better than the finger-tips where it can be used for massage. Recent periarticular exud-

¹ Read at the Surgical Section of the Suffolk District Medical Society, February 3, 1897.

ations are thus speedily dispersed and absorbed, which might in time have become organized, while superabundance of intra-capsular fluid is pressed into the absorbents, the function of which within the joint is increased by the pressure from without and by the acceleration of their current from the massage above the joint.

In recent sprains and synovitis this method is rational, for it quickly relieves the heat, the pain and the swelling, and takes the pressure off the nerve filaments. The comfort to a joint, even after a single sitting, cannot be believed unless felt. The good effects of the massage are continued by means of a bandage well applied; but the pressure of a bandage alone, though it affords support, hinders the circulation by its continuous pressure, and will not take the place of massage, which, when rightly applied, is an intermittent pressure and an aid to the circulation.

Kraske has demonstrated that the application of a rubber bandage to the leg of a rabbit for six hours has produced hyaline degeneration of the muscle, from which they do not recover. If we want weak and atrophied muscles, let the bandage be continued after the swelling has disappeared. Rubber bandages I never advise except for temporary use, as when a patient with a weak joint wants to go sea-bathing. They are intensely disagreeable on account of the smell of the rubber combined with the perspiration which they produce. They are dangerous by literally strangling the tissues, for each turn, by its elastic tension and hug, represents much more compression than the force used in putting them on. Often I have taken them off and applied a domett (or cotton flannel) bandage, and always to the great delight and comfort of the patient. Bandages cut across the bias I used for a dozen years before I came unbiassed towards them. Take one in your two hands, and give it a pull, and reflect for a moment, and you will see that it stretches much more at the edges than it does in the middle; so that when it is applied it presses unequally; and soon after it is put on it is as loose and lacking in support as a rubber bandage is tight and uncomfortable. A domett bandage is firm, soft, warm and comfortable; and when you have put one on, you know what you have done, and a few extra layers of this will often take the place of splint and plaster.

Every man thinks his own method of massage and bandaging the best, as every housekeeper who cooks her own beans thinks they are the best. Under the plan which I have just outlined we will be agreeably surprised and somewhat disappointed to find that most sprains of even more than ordinary severity will get away from us inside of a week or ten days. The vast number of sprains of all degrees of severity that have recovered in from seven to nine days under massage would seem to prove either that rupture of ligaments and tendons, and laceration of muscles occur much less frequently than is supposed, or else that they are of much less serious import when treated by massage.

In 1877 I published the results of massage in 300 cases of sprains, and in 1884 of 400 more of all degrees of severity, treated by many different observers (most of whom were French, German, and Scandinavian army surgeons), in order to confirm the experience which I obtained in some of my cases. The invariable result in each and every case was that such injuries thus treated got well in one-third of the

time that similar cases did under absolute rest and fixation. Experience teaches that the sooner after a sprain massage is begun the quicker does recovery take place, and the less the tendency to subsequent weakness, pain and stiffness, which almost invariably follow after immobilization without massage.

Some careful physicians who are in favor of massage in sprains think it well to wait a few days while using hot and cold water or some other treatment before beginning massage. In this event I am not sure that the effects of massage are not more striking in arousing the limb from the lethargy and stupor into which it has been plunged by the shock of the accident. When this local lethargy and stupor have been prolonged for a month or six weeks, as must necessarily be the case when a limb is done up for a fracture, the immediate effects of massage in bringing the limb back from death to life, in starting anew the circulation, in awaking sensation and motion, are often remarkable. But sometimes — and alas! too frequently — under a plaster-of-Paris dressing, the connective tissue proliferates and assumes a plank-like hardness, a literal deadness, that is most discouraging to an intelligent massener and which is a sure sign of tedious recovery. I believe it is possible to prevent this by having the cast removed occasionally and the limb *masséed* without disturbing the fragments. Rest is necessary to produce ankylosis, and I do not see the need of allowing well joints to be imprisoned to such an extent that they will become stiff while a fracture above or below them is uniting, when a little precaution in the way of massage and passive motion might preserve the function of the limbs.

My distinguished confrères, Drs. Van Arsdale and Gallant, of New York, have treated 1,231 cases of recent sprains by means of massage, with better recovery in as many days as it took weeks under fixed dressings without massage. They obtained complete restoration of the functions of the limb with no subsequent weakness, stiffness or pain. Some of their cases were so severely injured that the massage had to begin under an anesthetic. They also obtained the best and quickest results in those cases in which massage was begun immediately after the injury, so that the patients did not know what they had missed in the way of prolonged recovery. Neglected cases, and cases in which splints had been used, gave very satisfactory results, but took much longer. Van Arsdale and Gallant, after *masséing* a sprain, have the limb rest for half an hour and then urge the patient to use it, presumably in spite of pain, after which it is kept elevated between the *séances* of massage, which are given twice a day.⁶ I prefer to put on a snug bandage and keep the limb at rest for a few days, unless the sprain be a slight one.

Patients are generally quick to recognize improved power of motion and to make use of it. If they do not, the manipulator can judge for himself by passive and resistive movements how much or how little the joint is capable of, and encourage or restrain motion accordingly. In recent cases it is preferable that the patients manifest the first desire to make use of the joint, for it is often impossible to tell how severe the injury may have been; and if patients are not of nervous temperaments, sensations and inclinations can generally be trusted. After due time for repair

⁶ Medical News, April 20, 1895.

has elapsed (in order to gradually increase the strength of the muscles as well as the confidence of the patient to use them), there is nothing better than resistive motion, alternately resisting flexion and extension or other natural movements of the weakened joint, while carefully keeping the resistance less than the strength of the contracting muscles, so that the patient may not recognize any weakness. It is rank nonsense to tell a patient to walk or use a limb that has been weakened by injury and long confinement in splint or plaster without gradually training the strength of it in the way just pointed out.

Sprains of the ankle, instep and knee seem to recover more quickly under massage than do sprains of the joints of the upper extremities. The fact that the joints of the lower extremities have to carry considerable weight while those of the upper do not, would seem to argue in favor of massage, for the use of a joint with pressure from above is a sort of automatic massage, which in the case of slight sprains of foot and ankle with a snug boot on may be quite sufficient to expedite recovery.

A curious feature that I have lately observed in several cases of sprains, muscular rheumatism and stiffness after fractures, is that coincident with improvement, there is an increase of tenderness on pressure around the joints and over the muscles. This is different from the acute pain caused by pressing over a joint but recently injured, or over muscles indurated with muscular rheumatism. I think it may safely be disregarded, or perhaps considered a good sign; for those cases in which I have seen it, all had returning suppleness of tissue and did well.

Do not think that any one can *masser* a sprain. No two cases of injured joints are exactly alike. The treatment must be varied to suit the case, the rudder must be turned so that the sails will catch the breeze in order that the port of recovery may be quickly reached.

CASE I. M. M., forty-five years of age, strong and muscular, while playing golf one Sunday afternoon, slipped and gave his right ankle a double twist. He immediately felt nauseated and had to lie down. He was in much pain all night, and sent for me early in the morning. I found much swelling, pain and discoloration below and around both malleoli. A hot bath, massage and a snug bandage was applied twice a day; and on the fourth day after the accident he went to business without crutch or cane, and walked up two flights of stairs to his lunch. He was not, of course, by this time entirely well, but so far recovered that only occasional massages were necessary afterwards. He made a good recovery notwithstanding that the same ankle had been sprained about a year before.

CASE II. Mrs. W. L., an active lady of strong muscles, fifty-six years of age, in descending the stairs of a hotel caught the heel of her foot on the brass cover, turned herself over on her foot and fell sideways downstairs. I saw her within one hour after the injury. The capsule of the ankle-joint was intensely swollen, and protruded in front of the external malleolus, and the patient had no control over her foot. The ankle was severely sprained, and it was impossible for her to walk or even put her foot on the floor. The tissues around the joint were extremely sensitive, and could not bear the contact of either hot or cold water. No evidence of fracture could be made out. I predicted greater swelling and a six weeks' stay in

the house, as the injury was certainly of such a nature from its mode of occurrence as to produce all the evils that are credited to a severe sprain. Massage was applied twice daily, and after this a snug bandage, and over this a splint. At the end of a week she could walk a little, and in ten days was going about freely.

CASE III. Mrs. W. B., fifty-five years of age, slipped on a curbstone and came down heavily, turning her foot inwards. She was in great pain, but managed to bobble home, a distance of twenty rods, with the assistance of two people. Eight days after this she was first seen by me. She had not been able to bear any weight on the ankle since the accident, and had worn a rubber bandage. There was great discoloration and swelling, most marked around the outer malleolus, and extending half-way up the leg. Absence of pain while the foot was at rest was marked at this time. Massage was given twice daily at first, which made the ankle comfortable and the patient grateful; and after the massage a cotton bandage was applied (with absorbent cotton under it) over the most swollen parts. At the end of eleven days she began to take a few steps, leaning on the back of a chair, having been in preparation for this for a few days by means of passive and resistive motion while lying down. She made daily progress in walking.

But in the meantime the swelling had been unusually slow to decrease, and it was not until the fifteenth day after I first saw her (the twenty-third day after the accident) that it was sufficiently abated so that the outer malleolus could be made out. This was found to be wider and flatter than the other, to spring on pressure, and was very sensitive, but there was no crepitus. Suspecting fracture without displacement, I called to see the late Dr. R. M. Hodges, who then lived quite near to the patient. After my description of the case he thought my diagnosis was correct, and we set a time for consultation. "How much can she use her ankle," he asked. "Walk about indoors," I replied. "Then you are doing first-rate; keep on, you do not need me." He was a man, we shall not look upon his like again.

The patient was kept awake a great deal by the illness of her husband. By and by symptoms of neuritis set in, and she had pain, burning and tingling, extending from the ankle up the outer aspect of the leg, which was worse at night. This was much relieved by massage as well as by a walk in the evening followed by an alternate hot and cold bath. Her disagreeable symptoms all improved, and at the end of twenty-five days she could go up and down stairs naturally.

Without splints or plaster cast this patient made a good recovery from a sprain with a crack in the external malleolus, and from a subsequent attack of neuritis while under great anxiety and losing much sleep.

CASE IV. I was called to the following case by his physician, Dr. Henry W. Broughton, on the 15th of November, 1894. The patient, Mr. P. F. L., was then eighteen years old, weighed 142 pounds and was of a highly nervous temperament. Six days before I saw him, while playing ball, he was pushed down and sprained his right knee, but could not tell which way the leg turned. He had been in great discomfort ever since, and unable to sleep, though he did not complain of pain so much as restlessness. The leg had been put in a plaster-of-Paris dressing, which he could not

tolerate; and this was laid aside, for a curved ham-splint. Moderate attempts at flexion or extension, bending the leg in and out, did not cause pain. The range of motion was very slight. Stronger attempts to move it passively and especially to bend the leg in at the foot and out at the knee, caused pain, which was referred to the outer aspect of the knee and to the insertion of the outer hamstring muscles; from which we inferred that the knee had probably been sprained by the leg turning inwards and the knee out. There was much discomfort in the muscles on the outer aspect of the thigh and pressure on the condyles of the femur caused pain.

We learned that within the previous three months he had given his knee several jerks so that it was still in an irritable condition when he hurt it this last time. There was much heat and a great deal of effusion, tense and fluctuating, which was most marked above the knee, distending the synovial sac on the front of the femur beneath the tendon of the quadriceps extensor muscle. Under daily massage and bandaging the effusion went down and the circumferences rapidly decreased as a few measurements taken from my notebook show.

	Centre Patella.	Above Patella.	Below Patella.
Well knee	14 in.	13½ in.	12¾ in.
Nov. 15, 1894, injured knee	16	15½	13½
After 30 minutes' massage	15½	15½	13½
Nov. 18th, before massage	15	15½	13½
Nov. 18th, after massage	14½	15	13
Dec. 1st.	14½	14½	12½

Further decrease of circumference did not take place. Morphia and phenacetine seemed to have no effect in quieting the patient. Large doses of sulphonal succeeded a little better. Three days after massage was begun he rested well without any hypnotics; and by the fourth day the improvement in the knee was so marked in the diminution of the swelling and the feeling of the tissues, that pushing the leg against resistance was begun. On the following day he pushed so vigorously that we allowed him to walk on crutches, which he did, bearing some weight on the lame knee.

December 1st. Had no massage for five days, and was then going about with one cane. Had no pain while walking until he got tired.

December 26th. There was evidently a good deal of induration and thickening on the outer aspect of the thigh above the knee-joint. The margin of what seemed to be the synovial capsule on the outer and anterior aspect of the thigh felt hard and sharply defined, making one think that perhaps there had been a rupture of the vastus externus. But there had been no sudden pain, and he could contract his quadriceps extensor group, though not strongly.

For the past eight days, he had been going about freely with one cane. The leg would only bend at this time to a right angle, and it could not be freely extended. He then told me, what we had not learned before, that *this was as much motion as it had before it was injured*, and that it had been a troublesome knee for about a year and a half. My suspicions were aroused, and meeting his physician a few days later I suggested to him the possibility of the patient having a sarcoma. Very soon after this he was taken to the City Hospital, where his leg was amputated. It was found that the lower end of the femur had been converted into a large involucrum by a subperiosteal sarcoma, which had burrowed into the medullary canal,

leaving an outside shell. A year later he died of sarcoma of the lungs; and history shows that this is sadly too often the ending of these cases where no massage has been used.

After the first eight days that I attended this patient massage and bandaging were continued but once or twice a week till the 26th of December. The leg was amputated January 5, 1895. Doubtless the disappearance of the effusion made the diagnosis easier for the surgeons, who had not previously seen the case. One of them thought that this was a case where massage might have been more honored in the omission than the performance. Possibly. Another who examined the patient told me that massage could not do any harm in such a case. An orthopedic surgeon of large experience who did not know of this case, when asked in the abstract as to the danger of massage accelerating the spread of sarcoma cells into the general circulation and producing a metastasis of the disease in other organs, expressed himself freely to the effect that it would not make any difference. Where the risk is already so great of diffusion of sarcoma cells and the reappearance of the disease in some other organ, I think any of us would be willing to run a little more risk if massage or any other treatment would do as well for a sarcomatous limb that had been repeatedly sprained as this one had been, and give us the use of it again for a few weeks before having it cut off.

This subject is by no means exhausted, for so-called sprains of back, hip, shoulder and other joints would require further consideration.

From the foregoing the following conclusions would seem to be justifiable:

(1) A sprain is a wrench or twist of a joint; a sudden, partial displacement of two articulating joint-surfaces, followed by immediate replacement.

(2) The symptoms are pain, swelling, discoloration, and usually heat, with impaired motion.

(3) Its diagnosis may be obscured by the swelling, which may conceal a fracture underneath.

(4) Whatever will quickly reduce the heat, the pain and the swelling — such as massage, snug bandaging, and elevated position of the joint — will proportionately make the diagnosis easier.

(5) The means just mentioned are therefore not only valuable for diagnosis but also for treatment; and their use in many cases of sprains of all degrees of severity shows that they recover in one-third of the time that they require under absolute rest and fixed dressings without massage.

(6) Even a sprain of a joint previously weakened by malignant disease may be rapidly ameliorated by massage, and useful motion gained before amputation.

A BRIEF HISTORICAL RETROSPECT OF THE EXAMINATION OF THE URINE IN ANCIENT AND MODERN TIMES.

BY THEODORE WM. SCHAEFER, M.D.,

Professor of Chemistry, University Medical College, Kansas City, Mo.

MOST works on urinalysis and urinary diagnosis are devoid of important historical data. As far as the writer is aware, no book has been published in the English language on the examination of the urine which contains an historical introduction.

It is to be hoped that this brief, cursory historical retrospect will stimulate others in studying medical history, a very instructive and fascinating study. It is a fact, which cannot be denied, that medical history is very little studied in this country and does not receive the attention which it deserves.

In ancient times, according to the history of medicine, the examination of the urine was held in great esteem by the common people and was accordingly practised by physicians, in the days when there were no microscopes, by simply reading the disease off from the urine by looking at it. The *modus operandi* of looking at the urine is called *uroscopy*, and was much practised in ancient times.

It is highly probable that in the days of the Pharaohs, when specialism in medicine was so complete, that the ancient Egyptian physicians practised uroscopy. They used urine internally as a medicament, which fact should not surprise us at all, for the common people have still faith in the efficacy of urine as a remedy for certain diseases, and urine mixed with brandy is occasionally swallowed down in spite of our so much praised days of enlightenment, progress and advanced therapeutics.

The ancient Chinese and Hindu physicians practised uroscopy. The early East Indian physicians were acquainted with diabetes mellitus. In the days of the Roman Empire, when the number of physicians was as considerable in proportion to the number of inhabitants as it is to-day, there were many specialists, among whom were also those who examined or rather looked at the urine.

Celsus, the Roman, and especially Aretæus, of Capadocia (about A. D. 30-90), described diabetes and diseases of the bladder.

Quintus Serenus Samonicus (died A. D. 211) wrote a medical poem, entitled "De Medicina Præcepta," in hexameter verse. In this poem he laments goat's urine internally for stone in the bladder.

"Si vero horrendum vulnus fera fecerit aspis,
Urinam credunt propriam conducere potu."

"Siquis hyoseyamum gustarit, lacte capellæ
Exhausto, rabidos poterit nuncere furores."

During the Middle Ages, the urine was investigated by inspection, and Alexander, of Tralles (525-605), discusses in his "Twelve Books of Medicine," the subject of urinary sediments quite fully.

Theophilus, who lived under Heraclius (610-641), wrote a treatise "On the Urine."¹

Stephens, of Athens (640), in his treatise "On the Signs of Virginité," mentions the Egyptian superstition, that a reliable diagnostic sign of virginity may be found in the fact that peas upon which a virgin has urinated germinate, while the contrary condition of sexual purity may be proven by the failure of the peas to sprout — apparently a very accommodating doctrine when we consider the germinative power of peas!

The treatise *Περὶ ούρων*, *De urinis*, commonly ascribed to Theophilus, is probably the work of his disciple Stephens, and is the earliest treatise on uroscopy which has been preserved to our day (Handerson).

The Arabian physicians had recourse to mysterious procedures, and busied themselves with uroscopy and astrology, branches which were subsequently transmitted by them to the West. A regular physician

would rarely meddle with surgery. The Arabian physicians enjoyed a good reputation as prognosticians and diagnosticians. What kind of diagnoses they sometimes made may be inferred from the following anecdote:

Thabet ibn Kora (836-901) diagnosticated a disease between the ribs and pericardium in the following manner: "I showed him my urine glass, and he saw in it what was hidden between my ribs and pericardium." And without needing to trouble himself, like us poor doctors, with anatomy, pathological anatomy, auscultation and percussion, and even the post-mortem, "the concealed disease appeared to him as a stain on a polished sword looked to the eye," — a better result than we can attain with all our accessories!

Nokter, of St. Gall, who lived in the ninth century, famous as the greatest savant of his age, a musician, astronomer, mathematician, poet and theologian, well versed in the Greek and Latin languages (at that time a great rarity), was well known also for his cures and his uroscopy.

The statutes of the Hospital of St. John, of Jerusalem (in 1181), provided that the four physicians who were employed there should be skilled in uroscopy. Uroscopy was taught in the universities, and the price for an "examination" of the urine at Frankfort, Germany, in 1424, was about twenty-four cents.

In the sixteenth century, uroscopy was recognized as an honorable occupation of the physician. It was first promulgated by Galen (A. D. 131-201) that the condition of the natural forces can be determined from the condition of the urine, as that of the spiritual forces from the pulse; and that in the same way the health or disease of each important organ may be determined.

In support of such nonsense, which was especially current in Germany, such men even as Joubert, Capivaccio, Thomas Fyens (1567-1631) at Louvain, and Hercules Sassonia (1550-1607), declared themselves. More numerous and weighty, however, were its opponents: Joh. Lange, Diomedes Cornarus, Horekovicz, Clementius Clementinus (about 1512), at Rome; Christopher Clauer (about 1531), of Zürich; Euricius Cordus (1486-1534), of Zimmerhausen in Hesse (lived about 1520 in Erfurt, then in Marburg, and died 1534 in Bremen); Franz Emerich (about 1552), of Vienna; Bruno Seidel (about 1562), professor in Erfurt; Wilhelm Adolph Scribonius (about 1585), in Marburg; Siegmund Koelreuter (about 1574), in Nuremberg; and Peter van Foreest (1522-1597), of Alkmaar, in northern Holland. Such were the most famous of the opponents of this doctrine, who contended that the causes of disease and diseases themselves, etc., could not be determined from the urine, since temperament, season, mode of life and age had a great influence upon its excretion (Baas).

"Carry his water to the wise woman," says Fabian in "Twelfth Night"; and to the question of the doughty Sir John Falstaff, in "King Henry IV," "Sirrah, you giant, what says the doctor to my water?" His page replies: "He said, sir, the water itself was a good water; but for the party that owned it, he might have more disease than he knew for."

On which the learned Stevens makes the following comment: "The method of investigating diseases by the inspection of urine only was once so much the fashion, that Sinacre (1461-1524), the founder of the College of Physicians, formed a statute to restrain

¹Outlines of the History of Medicine and the Medical Profession, by John Hermann Baas, M.D. Translated from the German by H. E. Handerson, M.D.

apothecaries from carrying the water of their patients to a doctor, and afterwards giving medicine in consequence of the opinions they received concerning it. This statute was soon followed by another, which forbade the doctors themselves to pronounce on any disorder from such an uncertain diagnosis.

"It will scarcely be believed hereafter, that in the years 1775 and 1776 a German, who had been a servant in a public riding-school (from which he was discharged for incompetency), revived this exploded practice of *water-casting*. After he had amply increased the bills of mortality and been publicly hung up to the ridicule of those who had too much sense to consult him, as a monument of the folly of his patients, he retired with a princely fortune, and perhaps is now indulging a hearty laugh at the expense of English credulity."

Why should it not be believed? Do not "eminent" doctors now profess to diagnosticate, not only diseases, but even conjugal compatibility, by a microscopic examination of the blood? And this not in 1775, but the year of our Lord 1886! (Handerson.)

[Twenty years ago the writer of these lines knew of an old German quack in the city of Baltimore, who practised the ancient art of uroscopy. It was surprising to see the number of people, from all quarters of the city, who would flock to him for treatment. Old and young were requested to bring their "water" along. A dentist, who lived only a few blocks away, believed in the emetic powers of urine and administered urine to his sick children to produce emesis.]

During the Reformation, uroscopy or *Brunnenschau*, as it was then called in Germany (Luther had translated the Hebrew term for the meatus urinarius in women by *Brunnen*), and urinary prognostics were an everyday business, so that in pictures the doctor and urinal always stood beside each other. These noscopists found their doggerel immortality in the right royally pitiful rhyme of the "Theuerdank," an allegorical poem by Melchior Pfünzing, published in 1517, though these same things are done frequently enough also to-day in both open and secret practice. Handerson has translated two of these verses into right royal and pitiful English doggerel, as follows:

"Doctor! His water you now have surveyed:
Dare you promise me truly that he shall be made
Well, sound and free from his present disease?"

The doctor said that, according to the indications of uroscopy, the disease might be a fever, and that, with God's help, he would cure the patient. But,

"After the teachings of Avyzen,
Weak drugs alone must be given to him.
Strong drugs, I ween, will not answer so well,
For a simple complexion within him doth dwell!"

The following account also gives us a pretty picture of the condition of medical matters at that time. Besides all sorts of so-called physicians, many itinerant Jews carried on business: "The shameless, idiotic Jews also, though banished from the land, had nevertheless no hesitation in travelling and riding about in Würzburg and the adjacent places, their urinaria in hand or carried upon the pommel of the saddle, professing and boasting, whenever one was sick they would from a simple examination of the water, diagnosticate and make known the disease and its causes, whatever length of time it might have existed. Thus they cheated the poor people, and, indeed, sometimes the nobles and the lords, out of large sums of money

... which is pitiable and disgraceful, to be overrun and mocked at by such heathens, who should more properly be persecuted by the Christians. After such management, and after, if possible, invoking the aid of the magic spells of both males and females, then for the first time recourse was had to the doctor, in order to have him examine the water." A system, which, with some variations depending upon the times, is frequently followed to-day!

Physicians-in-ordinary were appointed especially to inspect every morning the "water" of their gracious lord. This was done in order to ward off any impending danger which threatened their most gracious master, and prophylactic measures were at once instituted when the appearance of the urine indicated the slightest change of color. From this exquisite humor and salty fluid were made not only the diagnosis of the disease, but also its procatactic (exciting) causes—something in the style of that doctor of the present day who, by holding up before his eye the urine glass, diagnosticated a fall down a flight of twelve steps. Moreover, in this way was determined the existence or non-existence of pregnancy—"a deceit of which the physicians themselves were conscious," which fact renders the disgrace only the more indelible. Here and there a urinary glass was the sign of a physician (Baas).

Dr. Thomas Willis (1622-1675), after whom the "Circle of Willis" is named, lived in the time of Charles II of England. He determined the sweetness of diabetic urine in 1674, and is generally admitted to have been the first who noticed this particular pathological condition of the urine.

In the beginning and middle of the seventeenth century, prescriptions a yard long flourished in daily practice, with ten or more ingredients. This medieval fashion still obtains in certain quarters of our own country.

Ananias Horer (1721), a contemporary writer of those times, says, "We find excellent practitioners who permit the sick to bring their urine to the house and from its appearance diagnosticate disease." And Job. George Zimmermann (1728-1795) said that from Russia to Switzerland he was regarded as a great practitioner, who had, instead of books, a large number of urine glasses in which the doctor urinated himself.

Uroscopy was practised far into the eighteenth century in Germany. The "*Urinbüchlein*" of Th. Majus was the text-book of the day. It is worthy of interest, from an historical standpoint, to mention just here the fact that it was Contugno, in 1770, who first employed the boiling test for the detection of albumin in the urine.²

Pole, in 1775, and Mathew Dobson in the same year, demonstrated the existence of grape-sugar in the urine, and John Rollo (of Woolwich, an English naval surgeon) wrote an extended monograph upon this subject.³ "Mathew Dobson actually obtained sugar from urine."⁴ Cowley (in 1788) and Frank (in 1794) were familiar with glycosuria. William Prout (1785-1850), of London, England,⁵ besides describing diabetes mellitus in 1825, proved that the acid in the stomach was hydrochloric acid in 1824.—Dr. John Blackall (1771-1860), of Exeter in Eng-

² After Purdy, Practical Urinalysis and Urinary Diagnosis. The urine was boiled in a spoon.

³ An account of Two Cases of Diabetes Mellitus, etc., London, 1797.

⁴ Tyson: The Practice of Medicine, p. 750.

⁵ Diseases of the Kidneys, 1843.

land, repeated Contugno's heat-test for the detection of the presence of albumin in the urine (1813) in cases of nephritis.

But it was Dr. Richard Bright (1789-1844), of London, who first placed the examination of the urine upon a solid, scientific basis, and who reformed our renal pathology by his excellent, masterly description of the disease which bears his name. It was Bright who has given urinalysis a new path, and he deserves a place among the first and foremost physicians in the history of medicine.

Johann Florian Heller (1813-1871), of Vienna, after whom the nitric acid test for albumin is named, invented the urinometer in 1849. Claude Bernard (1813-1878), the celebrated French physiologist, made his classical experiment by producing glycosuria artificially by puncturing the floor of the fourth ventricle. The well-known color-test for bile with nitric acid is named after Leopold Gmelin (1789-1853).

Justus von Liebig (1803-1873), the greatest of German chemists and founder of university laboratories, has given to urinalysis a method for the quantitative estimation of urea.

The names of Pettenkofer, of Trommer, of Fehling, of Heidenhain, of Ludwig, of Vogel, of Roberts, of Garrod and of Tyson are known to every medical student. Paul Ehrlich (born 1854), one of the opponents of the phagocyte theory of Metschnikoff, has given to urinalysis a ready method for making a positive diagnosis in typhoid fever.

The diazo-reaction of the urine was first suggested by Ehrlich in 1882. Tyson says in his excellent work on "The Practice of Medicine," page 29, that he "never found it absent where the test was made sufficiently early."

Before closing, I should not forget to mention the names of Jacksch, who has written a valuable work on clinical diagnosis; of Maixner and of Kuhn.⁶ These three observers have laid down the law that peptone is always present in the urine when suppurative processes are going on in the body.

In this connection I should not fail to mention also the name of Charles W. Purdy, M.D., who has written one of the best works in the English language on "Practical Urinalysis and Urinary Diagnosis," which was first published in 1894. — Urinalysis has made rapid strides in recent years, and the day has at last arrived when the examination of the urine in disease can no longer be ignored by the physician. Chemical and microscopical analyses have been made subservient to other methods of diagnosis in a considerable number of diseases. We are able to establish the existence of minimum quantities of matter, thereby making a positive diagnosis, which is not possible by any other method at our disposal.

ABORTION DANGEROUS IN ENGLAND. — A member of a distinguished family in England telegraphed to a no less distinguished dermatologist: "How can I abort eczema?" The police, getting wind of such a dispatch being sent, and thinking "Eczema" was a woman's name, placed the gentleman under arrest. The tragedy itself was, however, aborted by a prompt explanation that ex-Emma and eczema were not the same. — *Medical Record*.

Medical Progress.

RECENT PROGRESS IN GENITO-URINARY SURGERY.

BY F. S. WATSON, M.D., BOSTON.

SPONTANEOUS RUPTURE OF THE BLADDER.¹

MR. ARCHIBALD CUFF, reports, from the service of Mr. Charles Atkins, Sheffield Infirmary, a case of spontaneous rupture of the bladder, with operation and recovery. The patient, a male aged forty-seven, had a long-standing stricture of the urethra, dating back to a gonorrhea fifteen years before. For three years he had had vesical tenesmus, dysuria, and attacks of pain in the lower abdomen and loins.

Two weeks previous to entering, on lifting a ladder he felt something give away in the lower part of the abdomen; twelve hours later there was severe pain, and on the following day repeated vomiting and chills, and a rise of temperature. At the same time a tumor appeared in the hypogastrium. Vomiting ceased in a short time. When admitted, the temperature was 106°, pulse 104. There was an ill-defined tumor extending from the symphysis pubis nearly to the umbilicus; abdominal walls tense; no tenderness. The catheter drew a small quantity of alkaline and turbid urine.

An incision was made as for suprapubic cystotomy. Upon entering the abdomen a thick mass was encountered, which apparently consisted of connective tissue and inflammatory exudation. It contained a series of cavities filled with bloody urine, one of which communicated by a small opening into the bladder; at the upper part of the mass was another cavity containing foul pus; all the cavities were freely opened and drained.

The patient made a good recovery. The mass diminished to a small lump, and the abdominal wound healed. The urine became clear, and the patient was relieved of his symptoms.

The author considers this to have been a case of a bladder sacculated by long-continued distention due to stricture, and rupture following upon unusual muscular effort.

SPONTANEOUS RUPTURE OF THE FEMALE BLADDER.²

The patient, a woman of thirty-eight years, was operated upon December 5, 1896, for hemorrhoids. No urinary retention followed the operation. On making a sudden movement in bed she felt something give way in the lower part of the abdomen, which was soon followed by severe abdominal pain. Abdominal distention and diminution in the quantity of urine soon took place. There was no rise in temperature. The patient died three days later.

At the autopsy a large quantity of urine was found in the peritoneal cavity; no peritonitis, tuberculosis or other disease of the peritoneum. The bladder was empty. In the median line of its upper and posterior surface was a oval ulcer with thickened edges, an inch long and half an inch wide. Its base was formed by the mucous membrane of the bladder, in the centre of which was a small perforation through which the urine made its escape. Report as to the nature of the ulcer was reserved for further examination.

RENAL TUBERCULOSIS.³

The writer states the channels of invasion by which the tubercle bacilli reach the kidney to be three: first, and much the most frequent, by the blood; second, "ascending urinary infection"—by direct extension from the lower part of the genito-urinary tract; third, access to the parenchyma through the capsule, by extension from some neighboring organ.

In connection with the first of these—invasion through the blood—the question of the infection of the fetus through the blood from the mother during intra-uterine life, is decided as being practically established, though the inheritance of a dyscrasia is said to be the much more usual method of allowing subsequent establishment of the disease by rendering the possessor of the dyscrasia more receptive of it than are other individuals. Of the abdominal organs the kidney is stated to be that which is the most frequently infected. The bacilli which have originally made their entrance—ordinarily through the lungs or the alimentary canal—are taken up by the lymph-channels, passed through the veins to the arteries, and finally presented to the glomeruli of the kidney for elimination.

In the second—the ascending form—there seems to be a natural tendency for the disease to reach out toward the ureters, and to ascend through them or their lymph-channels to the kidney.

The third method—that of extension from neighboring organs—is less well established. The renal capsule seems to offer an efficient barrier to the invasion of the bacilli.

In examining for tubercle bacilli, the fact they are to be found in the powdered dust of the small calculi that are sometimes passed, when they are not discoverable in the urine, is noted.

The rarer forms of renal tuberculosis are stated to be as follows: renal epithelial tuberculosis; renal ecchymotic tuberculosis; a special form of tuberculous nephritis, due to compression of the uriniferous tubules by a process of sclerosis; tuberculous renal cicatrization; glomerulo-tuberculosis.

Morris gives figures from 2,610 autopsies at the Middlesex Hospital as to the frequency of renal tuberculosis. Among these were 44 cases of renal tuberculosis—29 of which were of the miliary, and 15 of the caseating form. Of the former, all showed tuberculosis of other organs, and both kidneys were involved in all but one. Of the 15 of the caseating form, two were primary in the kidney; in one of these there was no tuberculous disease elsewhere than in the kidney. Both kidneys were affected in 8 cases.

In a total of 125 cases of post-mortem examinations, of which the above mentioned form a part, more than half showed both kidneys to be involved.

The writer found 23 cases of renal tuberculosis in a total number of 567 autopsies at the Presbyterian Hospital, there being altogether 68 cases of tuberculous disease of one kind or another.

In 8 of the 23 cases of renal tuberculosis, one kidney only was involved.

The evidence for and against the view of Cohnheim, Khalden and others, namely, that tubercle bacilli brought to the kidney by the blood can be passed through it into the urine without injuring or infecting the organ, is presented and examined.

The practical point involved in Cohnheim's proposition is, that tubercle bacilli may exist in the urine without necessarily implying infection of the kidney.

Under symptomatology, attention is called to the different grouping and development of the symptoms, according to the mode of the invasion of the disease. Thus, when it is through the blood-channels there may be no symptoms of importance until the disease is far advanced, even to the formation of a palpable renal tumor. In the ascending variety, on the other hand, the renal infection will have been preceded by a most painful and exhausting train of symptoms, dependent upon the presence of disease in the bladder and the lower urinary tract.

The symptoms which aid in establishing a diagnosis are summarized as follows: pallor and emaciation, edema of the feet and legs, moderate pyrexia and night-sweats, polyuria, dysuria, pyuria with an acid urine, turbid urine seen to issue from the ureter on cystoscopic examination, an appreciable enlargement of the kidney, or a palpable tumor (whether tender or not), the discovery of tubercle bacilli in the urine drawn by a ureteral catheter, reaction to tuberculin injection, moderate albuminuria.

Under treatment, the writer says that nephrectomy, in cases in which the disease is shown to be limited to one kidney, even if the lower parts of the urinary tract are already involved, may be justified; ordinarily, however, hygiene, diet, outdoor life in an appropriate climate, give the patient the best chance of relief or recovery—or of retarding the process, at any rate.

Cresote, in gradually increasing doses, up to 70 or 80 minims daily, is recommended.

The following statistics are given of nephrectomy and nephrotomy in general, including their performance for tuberculous disease. The last table is that of 28 nephrectomies performed at Roosevelt and Presbyterian Hospitals. He cites 54 cases of nephrectomy, with a general mortality of 38.18 per cent.; also, 54 cases of nephrotomy, with an operative mortality of 12.72 per cent. These statistics of different compilers regarding nephrectomy are added:

ABDOMINAL NEPHRECTOMIES.

	Cases.	Mortality.
Tuffier	11	26.36%
Facklam	13	30.0
Vigueron	19	26.84

LUMBAR NEPHRECTOMIES.

	Cases.	Mortality.
Tuffier	45	28.33%
Facklam	75	28
Vigueron (primary)	65	40
Vigueron (secondary)	20	35

Presbyterian Hospital, nephrectomies since 1893, 15 cases.
Roosevelt Hospital, nephrectomies since 1893, 13 cases.
Total nephrectomies 28, recoveries 26, deaths 2 (7.1%).

A CASE OF TOTAL EXTIRPATION OF THE BLADDER.

Tuffier⁴ reports a case of total extirpation of the bladder (followed by recovery) for an extensive tumor of that organ.

The patient, a man forty years of age, had had urinary symptoms for three years, beginning with a sense of discomfort in the hypogastrium, which was soon followed by frequent and painful urination, which later

³ F. Tilden Browne: Presbyterian Hospital Reports, vol. ii, 1897.

⁴ Annales des Maladies des organes genito-urinaires, February, 1897, p. 130.

became almost intolerable. Hematuria first appeared at the end of two years, since which time there have been abundant hemorrhages at irregular intervals. Patient's general condition was fairly good at the end of the first year.

On admission, there was intense pain in the hypogastrium, radiating to the testicle.

October 6, 1896. Suprapubic incision revealed a hard tumor with friable surface, involving the walls of the entire left side of the bladder and the mucous membrane of the organ throughout. Free hemorrhage followed manipulation. The bladder was tamponed for twenty-four hours, and then drained for three weeks. The bladder was then extirpated. It was first tamponed with iodoform gauze. The abdominal incision was then lengthened, and it was further enlarged by a lateral incision on either side extending to the inguinal canal; the adhesions resulting from a former operation were broken down. The whole surface of the bladder was easily freed by the finger as far back as the points of entrance of the ureters. The bladder was then drawn upward through the wound, its neck was isolated by the finger, and the inferior vesical arteries and the ureters were clamped and cut. The bladder being drawn high up through the wound, it was possible to dissect off its peritoneal investment, and to free it thus from its attachments; after which it was removed. The clamps were then removed from the ureters. A catheter was introduced into each, and secured by a single suture passed through the wall of each ureter. The sutures were left long. A small incision was then made into the rectum on either side, and the ends of the ureters, together with their catheters, were led through these and out through the anus. The sutures were attached externally to a rod, to prevent their being drawn into the rectum. The cavity left by the removal of the bladder was tamponed with iodoform gauze and the abdominal wound was closed except at its lower portion.

The tumor proved to be an alveolar epithelioma. The patient's condition was critical on the second day, but thereafter improved. The packing was removed on the third day. At this time the urine was normal in quantity. On the sixth day the urine flowed through the abdominal wound as well as through the catheters. These were removed on the following day, and syphon drainage was placed in the abdominal wound. There was a fecal discharge through the abdominal wound on the ninth day, which persisted for two days and then ceased. On the twenty-first day a phlebitis of the deep veins of the right leg occurred, but did not seriously retard the convalescence, which was uninterrupted from that time. In the sixth week the patient was up and about; and thereafter he was well and practically free from all symptoms.

IMMEDIATE SUTURE OF THE BLADDER AFTER SUPRAPUBIC CYSTOTOMY.⁵

De Falaccos advocates immediate suture of the bladder after suprapubic cystotomy, and thinks it should be employed in almost every case, irrespective of the condition for which the operation was performed or the age of the patient, and refers to numerous successful cases. He prefers catgut for suture material, and uses a catheter *à demeure*. He allows his patients to get up at the end of a fortnight, as a rule.

⁵ Revue de Chirurgie, No. 8, 1896.

BOTTINI'S TREATMENT OF PROSTATIC HYPERTROPHY BY GALVANO-CAUTERY.⁶

Bottini describes his method and the instruments by which it is carried out. The bladder is emptied, and the urethra cocaineized with a one-per-cent. solution. The galvano-cautery instrument, shaped like a stone-searcher, is then passed into the bladder. The cauterizing part of the instrument is held against the portion of the prostate which it is desired to burn, and is heated to a red heat. The application of heat should not continue longer than one moment. The temperature of the cantery blade is increased every ten seconds. The outer part of the instrument which surrounds the cauterizing blade is kept cool by the passage through it of a stream of cold water. The operation is not painful.

After-treatment consists in drawing the urine with a catheter for the first twenty-four hours, and in washing out the bladder with a solution of boracic acid; later nux vomica is given by mouth. The slough separates usually in about twelve days, after which, as a rule, the patient is able to urinate spontaneously. When there has been much atrophy of the bladder-wall, much assistance is derived from the electric current and from intra-vesical douches of cold water.

He claims for this method the following advantages:

- (1) The rapid restoration of spontaneous urination, even where it has been absent for years.
- (2) The absence of danger, which he believes due to its aseptic nature.
- (3) The freedom from relapse.
- (4) Painlessness, and the avoidance of a general anesthetic.

Reports of Societies.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

PAUL THORNDIKE, M.D., SECRETARY.

REGULAR meeting February, 3, 1897, the President, DR. H. L. BURRELL, in the chair.

TERATOMA SPECIMENS.

DR. W. T. COUNCILMAN: The specimens which I have to show to-night came from a case which occurred in the practice of Dr. Lovett. The case is interesting both from a pathological and from a surgical point of view. The history is briefly as follows: A well-formed male child showed at birth a swelling of the serotum. This was at first taken to be a hydrocele, tapped, and a small amount of straw-colored fluid was found within it. The quantity of fluid, however, was entirely too small for it to really be a hydrocele. The tumor continued to grow, and in the course of a short while it was completely removed. When removed it was found to be a teratoma, that is, a tumor which is composed of highly organized tissue and in which all three of the germinal layers of the embryo are represented. It is interesting to find a tumor of this character, a teratoma of the testicle, in a child of that age because these tumors are rarely congenital. I think only four cases of congenital teratoma of the testicle have been reported. The wound healed perfectly, and the child did well a couple of months. At that

⁶ Archiv. für klinische Chirurgie, vol. liv, 1897.

time a tumor began to appear on the head. There was a tumor which first appeared close to the anterior fontanelle. It was apparently projecting from the cranium, and the tumor was partly removed. The tumor continued to grow very rapidly after that, and the child died about three months after the first appearance of the tumor. Examination of the tumor of the head showed that to be also a teratoma, and one which was really very much more complicated in its structure than the tumor of the testicle.

First, about the position of the tumor of the head. This mass of tissue which I have here represents a section of the tumor, one-half of the tumor. This is a portion of the frontal bone. The mass of the tumor is partly covered by the skull, which is very much thinned and eroded; and in places the tumor projects from the skull. Beneath the tumor one can see a smooth membrane, which is the dura mater; so that the tumor is attached to the dura mater, more or less attached to the skull, and it had compressed the brain. One of the points of interest about the case is the enormous compression of the brain and the fact that this compression had not produced any symptoms whatever during life. The convolutions of the brain were perfectly flattened; the great mass of the brain was pressed over to the left side, and the brain was exceedingly misshapen. The brain was, however, of the normal weight, and a careful microscopic examination showed the absence of any degenerative processes.

So that we have two tumors, one of the testicle and one of the head; and the two tumors followed shortly after one another. The tumor of the testicle was completely removed, and it was at first supposed that the tumor of the head really represented a metastasis of the tumor of the testicle. An examination of the tumor of the testicle and an examination of this tumor would show the impossibility of any metastasis from one to the other. The tumor of the testicle was of a more or less solid, more or less cystic, structure; and in the tumor almost all the tissues which one finds in the body were represented, and some of the tissues were built up to a very high extent. For instance, in the tumor of the testicle there was a structure which very closely resembled the retina, there was a quantity of striated muscular fibre, bone, cartilage and tissues which apparently represented in a rough way the trachea and even the intestinal canal—all in this small tumor. The tumor of the head is of a more or less cystic structure. There are numerous cysts here. Some of these cysts are lined with perfectly well-formed epithelium; some of them contain hairs. There is a quantity of bone in the tumor, cartilage, and a great deal of brain tissue—a tissue which really represented comparatively well-formed brain, certainly brain which would correspond to a comparatively late period of fetal brain. Among other structures there was a perfectly well-defined portion of cerebellum and a portion of the choroid plexus, so that from the complexity of the structure of the tissue which we have here we can be sure this did not result from a metastasis of the tumor of the testicle, because we always assume that a metastasis of a tumor is due to the conveyance of certain cells of the tumor from one part of the body to another by means of the blood or of the lymphatics, these cells being deposited in another part of the body and growing and developing a tumor similar to the first. Such a tumor as this could not have been due to a deposit of single cells, because the tumor,

if it were a metastasis, had not only single cells, but masses of tissue must have been deposited; and we know such tissues could not pass through the pulmonary circulation. At the autopsy there was no metastasis in the lungs or any place else in the body.

A very interesting point is in regard to the origin of these tumors. How can we explain the formation of such a tissue as we have here, in the first place in the testicle and after that in the head? With regard to these tumors of the testicle a great deal of work has been done recently; and careful investigation has shown that many of the tumors of the testicle known as cystochondromas, are more or less solid tumors of the testicle. If we examine them carefully, we shall find within the tumors tissues which correspond to all three of the germinal layers. How can such a tumor develop in the testicle? There is no way of explaining that in accordance with most of the theories of tumors. Of course, we can exclude trauma with regard to such a tumor. We can exclude the fetal inclusions in the ordinary sense of the word, because there is no way in the development of the testicle by which tissues belonging to the three germinal layers could be included. The testicle develops from the endothelium of the body cavity, and there is no possible way in which cells belonging to the mesoderm, endoderm and ectoderm could have been included in the testicle.

We have an analogy in the so called dermoid tumors of the ovary, those tumors in which we have cysts lined with epithelium containing hairs or epithelial products. It has been shown that these tumors of the ovary really are never true dermoids. Along with the tissues belonging to the epithelium there is always tissue which belongs to the mesoderm and tissues which belong to the endoderm. The majority of the so-called dermoids of the ovary are not simple dermoids; they are true teratomata in that all three of the germinal layers are represented. In the ovary it is the same way as in the testicle. How can we explain these tumors in the ovary? We cannot assume in the case of the ovary either the possibility of cells belonging to the epiderm or cells belonging to the endoderm being included within the ovary. The ovary is developed, as the testicle is, from the endothelium of the body cavity; and with regard to the ovary the possibility has been suggested that these tumors which we have in the ovary really represent a pathogenetic fetal development. There is an old theory with regard to these tumors, that they really represent an abnormal development of the fetus, resulting from impregnation in the ordinary way; but that is absurd.

Baldat supposes that under certain conditions the ova within the ovary can begin to develop and can develop such structures as we have here, that it is a parthogenetic fetal development. We know that the development of the ova without sexual congress takes place in a number of the invertebrates, and usually takes place for a time, and the product gradually becomes more fetal until sexual congress takes place again. That is known as the alternation of generation; and he supposes that under certain conditions this can take place in man, resulting in the production of the teratomata of the ovary. We know, of course, that all sorts of cells can come from the ovum without fertilization, and the cell in the ovum before it undergoes fertilization undergoes a certain change. If we suppose this to be the ovum and this the nucleus, that

nucleus before fertilization undergoes a certain change by which the so-called polar bodies are extruded from the ovum. The ovum in the beginning is a bi-sexual cell; and before it becomes impregnated the supposed male part of the ovum passes out from the egg in the form of the polar bodies, and the chromatin of the spermatozoon enters to take the place of the chromatin that has been lost; and it has been suggested by some that this very imperfect impregnation can take place in the ovary; that when one egg prepares itself, so to speak, for fertilization, and extrudes its male part, that that male part can pass from this egg into another ovum, and the ovum which is so very imperfectly impregnated can go on in the development of such very imperfect tissues as we have in the case of these tumors.

But that does not explain the formation of the tumor of the head at all. We can see here also no tissues from which this tumor of the head could have arisen. It certainly did not arise from the skull, because we could not have brain tissue and all the other tissues which we have here in a tumor formed from the bone. There is no real connection of the tumor with the skin or with the dura mater beneath; so that this tumor has grown here as a parasite, as a foreign tissue, not in connect on with any of the other tissues. It seems very probable that here we must assume, that in the course of development certain cells which were separated from the developing ovum or from the developing embryo at a very early date had become included within the walls which cover up the medullary cavity, within the so-called medullary plates which are formed on either side of the inward extension of the epidermis which forms the medullary canal. It would be very much simpler to explain the process if we found this inside the dura mater, because we could then assume the possibility of its being a fetal inclusion, that is, that there could have been a very imperfectly developed fetus, which could have been entirely enclosed in the medullary cavity; but this is entirely outside the medullary cavity, and must have been included in some way in the plates.

This is, so far as I know, an absolutely unique case. I have gone through the literature very carefully of all the head tumors, and I have not found a similar one. These teratomas of the head are not very uncommon; but they are found sometimes within the cranium, even in the ventricles of the brain or at the base of the brain. They sometimes develop from the pituitary body, and in some cases they grow from the posterior wall of the pharynx, and project partly from the pharynx and partly into the brain; and here we must assume either that the imperfectly developed parts of a twin fetus have become included in the enveloping medullary plates which close in the medullary canal, or else that there has been a very early segmentation of the embryo, and certain cells before the differentiation of the germinal layers have taken place have been thrown off, and these single cells have become included in that way. One of the mysteries we cannot explain is why those cells should be there for a considerable time, for months, and then suddenly go on and grow and develop in this way. One of the most interesting things about the tumor of the testicle is the age of the individual. As I have said, such congenital tumors of the testicle are exceedingly rare. By far the majority develop from twenty to thirty years of age.

SPECIMEN OF A DERMOID CYST.

DR. PORTER: This specimen is from a woman, between fifty-five and sixty years of age, upon whom I operated to-day. She had had this tumor located in the suprasternal notch twenty odd years. It was situated low down, close to the notch, between the two sterno-cleido mastoids, and about as large as a mandarin orange, lobulated and extremely hard to the feel. It was a question of diagnosis; and after considering everything I could think of as originating in that region, I told Dr. Hubbard it was like a grab-box, and I did not know what we should find. On cutting through the skin the fat appeared very like the fat in fat necrosis — an entirely different yellow from ordinary fat; and after exposing the tumor pretty well up towards the thyroid cartilage and down close to the sternum, it commenced to ooze towards the lower part. I ruptured it accidentally; it proved to be a dermoid cyst, and the solid part is represented in the central portion, and the rest is of hair and sebum removed from the cyst. The cyst extended up on the left side of the trachea to a level of the upper border of the thyroid cartilage, I should say, but my landmarks are not positive. I found it extended well down in the anterior mediastinum, and I was obliged to leave the cyst wall there, as it covered in the large vessels of that region; and from it was growing hair which could be seen. I suppose that it is a sequestration dermoid. I find in Sutton that dermoids of the thorax are very uncommon. I should like to know Dr. Councilman's views of the case.

DR. COUNCILMAN: This tumor, as I understand it, developed close to the inner border of the sterno-cleido-mastoid muscle. Was there any skin or papilla alongside of one of the sterno-cleido mastoids?

DR. PORTER: No.

DR. COUNCILMAN: I should think that it would be very much more probable that the tumor had developed from one of the branchial arches (some remains of one of the branchial arches) than from the tissues left by the closing in of the walls from the growing together of the thoracic walls. A short while ago I had a very interesting specimen showing the remains of a small portion of a branchial arch. This was on the neck, just in the position where it should have been; and if we suppose that to represent the sterno-mastoid muscle, and here the sternum, there was a small projection at that point, and extending downwards into the tissues beneath there was a small mass which could be felt as an infiltration; and epithelial tissues which had not gone on to a typical development were found in the tissues immediately beneath that point. It seems to me it would be rather more probable to suppose that it did come from a small portion of epidermis which became accidentally enclosed from the imperfect closure of one of the branchial arches than to suppose with Sutton that it came from the accidental inclusion of the tissue in the formation of the thoracic wall, because these dermoids are more apt to be in the mediastinum. We find them in the abdomen and in the thorax which result in that way. One of the most interesting examples of a tumor which formed from portions of the branchial arches I had the good fortune to see some time ago. That was an enormous carcinoma of the neck which had developed not from the throat nor from the outside of the neck. It was a true carcinoma, which developed

rather high up in the neck; and it could only have developed from some of the remains of the branchial arches. The malformations which can come in that way from the branchial arches and the tumors which can arise from that, form a very interesting chapter in pathology. As I understand you, that did not go down?

DR. PORTER: Yes, and that is the point I wish to make.

DR. COUNCILMAN: I think it is possible that it may have developed as you supposed.

DR. DOUGLAS GRAHAM read a paper on

SPRAINS AND THEIR TREATMENT.¹

DRS. R. W. LOVETT and J. G. MUMFORD read papers on the same subject.²

DR. PADDOCK: I wish to express my pleasure in meeting the Surgical Section to-night. For the two years I had the honor of being the president of the State society I looked forward to meeting you. It was my duty during that term of office to meet the different district societies throughout the State. I began with the society in Barnstable, and visited the different district societies north and south, east and west, putting off meeting the largest society of the State, the Suffolk, until the last; but, unfortunately, it was put off too long, and I did not meet you until to-night when I am simply an ex-president. When I came to-night I did not anticipate receiving the honor which your President, Dr. Burrell, has conferred upon me by yielding to me his seat. I assure you I acknowledge the honor which he has conferred, and yield it back to him to close the meeting.

DR. BURRELL: A motion to adjourn is now in order.

Motion made and voted.

AMERICAN MEDICAL ASSOCIATION.

ABSTRACT OF THE PROCEEDINGS OF THE SECTION ON PRACTICE OF MEDICINE, PHILADELPHIA, JUNE 1-4, 1897.

FIRST DAY. — TUESDAY.

The Chairman of this Section was DR. J. H. MESSER, of Philadelphia, who, in his opening remarks alluded to the inspiration that the members must feel in meeting in Philadelphia, the early home of American medicine.

The first paper read was by DR. W. B. CANAC, of Baltimore, entitled

THE SCHOTT TREATMENT OF CARDIAC DISEASE,

in which he said that no satisfactory theory had ever been advanced to fully explain how this treatment met the indications and produced the results which were claimed for it. Schott himself explained it on the theory of the reflex action of the nerve centres; while Lauder Brunton and Ludwig had discovered that the muscular system had a capacity of storing blood equivalent to that of the internal organs and the skin, and explained the action of the Schott treatment on the ground that the resistant treatment and the baths combined stimulated the muscular system to such a degree as to relieve resistance in the peripheral circu-

lation; but the results obtained by the treatment at Nauheim are undoubted in reducing the size of enlarged and dilated hearts. The speaker said that this method of treatment had been introduced into the Johns Hopkins Hospital for the purpose of testing its efficacy not only in cases of heart disease, but in affections of the kidneys. The author reported the results of ten cases. Of these, four patients had died, two were not improved, one showed improvement only while under constant treatment, and in three the permanent results were most satisfactory. Some of these were cases of chronic nephritis in various stages of advancement, but all of the patients had either enlarged or dilated hearts. In connection with the Schott treatment various heart stimulants, such as nitro-glycerin, digitalis, strophanthus, and strychnine, were used as the indications demanded. The experiments showed that while extensive changes in the position of the cardiac beat were obtained in all cases, this effect alone did not imply permanent improvement.

DR. WM. OSLER, of Baltimore, opened the discussion by saying that in suitable cases the Schott treatment was undoubtedly of positive advantage. One objection to it was the difficulty in carrying it out, as the class of cases in which it is indicated are those of moderate dilatation of the heart without much degeneration of its muscular substance.

DR. SROCKTON, of Buffalo, held that the Schott treatment was dangerous when applied indiscriminately to cases of cardiac disease. He insisted that it be carried out with great caution. In the baths at Nauheim, the water is charged naturally with gas.

DR. J. H. HERRICK, of Cleveland, O., said the treatment had no definite reference to the cause of the disease. In the treatment some relationship to the causation of the trouble as well as the organic disease was demanded.

DR. MORRIS, of New York, had found enlargement and dilatation of the heart common, especially among beer drinkers. The Schott system of exercise was very beneficial in cases of gastralgia. In his experience it produces a marked effect in lessening the area of dulness of the heart in such cases.

THE PROGNOSIS AND THERAPEUTIC INDICATIONS IN CARDIAC DISEASE.

was the title of a paper by DR. D. L. ROCHESTER, of Buffalo, in which he classified all heart diseases into (1) disease of the cardiac valves, (2) disease of the blood-vessels, and (3) disease of the heart muscle. It had been his experience to have patients brought to him in conditions regarded as utterly hopeless; and by proper treatment he had been able not only to relieve them temporarily, but to give them years of comfortable existence. Even in the most serious conditions of cardiac disease, it is never prudent to give an unfavorable prognosis until an attempt has been made by proper treatment to improve the tone and strength of the heart muscle and the arterial walls. The treatment recommended by the speaker consists in absolute rest in bed, the free use of cathartics, diuretics, diaphoretics, baths, passive exercise, and a liquid diet. Proper nutrition and exercise he considered important factors in the management of the cases later.

DR. JAMES B. HERRICK, of Chicago, was a strenuous advocate of venesection as a therapeutic measure

¹ See page 593 of the Journal.

² See pages 594 and 595 of the Journal.

in these cases, believing that it is of especial value in cases of general edema and cyanosis. He reported three cases of myocarditis in which he had resorted to this treatment with beneficial results. In each case he had drawn from sixteen to eighteen ounces of blood. The improvement in all of the cases was prompt, and in two of them permanent.

DR. J. B. MARVIN, of Louisville, Ky., favors the use of strychnine hypodermically in cases of acute dilatation of the heart; and commencing with one-twentieth of a grain of the drug, he increases it steadily until the physiologic effects are obtained.

DR. J. M. UPSHUR, of Richmond, Va., advocated the use of nitro-glycerine alternately with the strychnine.

DR. WAINWRIGHT advocated blood-letting in extreme conditions due to heart disease.

DR. ROCHESTER, in closing the discussion, said he employed tincture of *nux vomica* as a heart tonic, giving it in large doses, gradually increasing up to one drachm thrice daily.

DR. C. F. HOOVER, of Cleveland, O., read a paper entitled

REDUPLICATION OF HEART SOUNDS,

in which he referred to the various theories that had been advanced from time to time to account for the phenomenon of double cardiac sounds.

DR. HENRY BEATTES, of Philadelphia, followed with a paper upon

THE USE OF DIGITALIN WITH REFERENCE TO THE DOSE.

He said that digitalis had long had the reputation of being a very uncertain drug. The contradictory physiological effects were due to the existence of elements in the crude drug having diametrically opposite properties. There were now upon the market two preparations of digitalin, one known as the German, or pure Merck, and the other as the French Merck. The former was readily soluble in water and alcohol, but not readily soluble in ether. The latter differs from this in not being readily soluble in water, and is also a more powerful drug, and necessarily must be given in smaller doses. One-tenth of a grain is the minimum dose for an adult, and one-half a grain the maximum dose. The author uses the German digitalin.

DR. J. H. HERRICK believes that digitalis or digitalin acts upon the heart through the pneumogastric nerves. He was opposed to the routine treatment of heart lesions by any drug, and more particularly by digitalis.

DR. HENRY TOULMIN, of Philadelphia, read a paper entitled

TRACHEAL TUGGING,

in which he classified his cases into (1) very slight up-and-down movement, (2) slight up-and-down movement, (3) tugging; and (4) extra tugging. He had examined 75 patients; and of this number 44 presented no symptoms which could be ascribed to this class; 19 belonged to Class 1, five to Class 2, two to Class 3, and five to Class 4. The speaker said that the phenomena of the moving of the trachea with the respirations or the pulsations of the heart were due, as a rule, to aneurism of the ascending aorta.

THROMBOSIS OF THE BLOOD-VESSELS OF THE NECK.

This paper was read by DR. HELEN BALDWIN, of New York, in which she reported the case of a colored girl, aged twenty, who presented the symptoms of pain in the left side of the neck and in the axilla. There was extreme dilatation of the heart, and panting respiration. The temperature, taken in the mouth, varied between 94° and 96.5° F., while in the rectum it was constant at 102°. The external jugular was plainly defined and had the feeling of a hard cord. The patient died on the tenth day, signs of pneumonia having manifested themselves. At the autopsy an enlarged heart was found, with well organized thrombi in both the external and internal jugular veins.

SECOND DAY. — WEDNESDAY.

THE SERO-DIAGNOSIS OF TYPHOID FEVER.

DR. WM. H. WELCH, of Baltimore, opened the discussion on this subject with remarks on the principles underlying sero-diagnosis, in which he directed attention to the importance of a proper diagnosis of typhoid fever in its early stages, particularly in the South, where the prevalence of malarial and continued fevers made the clinical diagnosis difficult. The discovery of the typhoid bacillus was not immediately followed by the practical results in diagnosis and treatment consequent upon the discovery of the diphtheria and tubercle bacilli. Numerous attempts had been made to obtain cultures of the typhoid bacillus. The first was by the juice of the spleen, withdrawn with a hypodermic needle; but the results were unsatisfactory, and the danger of injury to the organ was considerable. Cultures made from rose-spots were tried, but were unsatisfactory. The results obtained with cultures made from the blood were more apparent; but large quantities of blood, as much as 10 cubic centimetres, were required. With cultures obtained in this way good results had been secured in 27 per cent. of the cases. The Elsner method of obtaining cultures from the stools marked an advance in the diagnosis of typhoid fever; but it was disappointing in that its field of usefulness was limited.

The modern method of sero-diagnosis rested upon Pfeiffer's discovery of the principles of artificial immunity; but Pfeiffer's reaction, so-called, had nothing directly to do with the reaction in serum immunity. The principle of Vidal's test was that by the addition of one part of blood serum to ten parts of fluid containing the typhoid bacilli a reaction takes place whereby the bacilli lose their motility and clump together. It had been ascertained by Dr. Johnston, of Montreal, that this power of producing agglutination of the bacilli was retained by dried blood as well as fresh. Dr. Welch was of the opinion that the best method of obtaining the blood was by an incision, or by pricking the lobe of the ear, rather than by blisters or the opening of a vein. This power to cause agglutination of typhoid bacilli possessed by the blood serum of typhoid patients was also possessed by other serous fluids, as the serum from a blister or the fluid from a serous cavity. High temperature destroys the power of agglutination. It is an open question whether more importance should be attached to the loss of motion of the bacilli or to the clumping, some observers being of one opinion and others holding to the opposite belief.

Young cultures, not over twenty-four hours old, should be used in the tests, though still younger, from six to eight hours old, had been used with good results in some cases. The author prefers a middle course, and uses and recommends cultures fifteen hours old. As to the culture medium, it did not seem to matter very much whether agar or bouillon was used. The use of old cultures is, the speaker thought, a distinct source of error. The degree of saturation of the test was another point which should receive considerable attention. With a strong saturation the result is obtained more quickly, while with a weak saturation a time-limit of about two hours should be allowed. It was his experience that the reaction was more marked in thermostat-cultures than in room-cultures. The degree of saturation recommended by Widal was one to ten or one to fifteen, but later experiments have shown that dilutions of one to forty or one to fifty gave better results. The criticism had been made that the colon bacillus gave the reaction in some cases as strongly as the typhoid bacillus; but when there was any doubt in the differential diagnosis of the two diseases, the precaution should be taken of making the test with a weak dilution, as the colon bacillus had never been known to react with a dilution greater than one to forty. Another source of difficulty in some cases is the late appearance of the reaction. In the majority of cases it could be obtained in the first week, but undoubted cases of typhoid, confirmed by subsequent post-mortems, had failed to give positive reaction until the second or third week, and in a few cases the reaction had been absent altogether. The conclusion to be drawn from this was that a negative reaction is not conclusive evidence of the absence of typhoid fever. A third source of error was to be found in the fact that the blood of persons who had had typhoid fever retained the power of agglutination for a considerable time.

Finally, Dr. Welch emphasized the importance of precision in the test, but at the same time he thought the method might be so simplified as to be available for the general practitioner, so that a fairly accurate test might be made at the bedside.

DR. WYATT JOHNSTON, of Montreal, stated that his experience with the serum test covered over 600 cases, more than half of them typhoid. He believes that other diseases, such as cholera and bubonic plague, will be shown to have a reaction. He has been led to devise the method of dried-blood tests on account of the distance that specimens had to be sent for examination; and it was found that the dried blood could be sent by mail. He believes that dried blood clumps more readily than serum.

An important point was the alkalinity of the culture; as, if it were acid, the reaction would not take place. Young cultures should be used in preference to old ones. With proper cultures, if loss of motion took place without clumping, it might be regarded as a pseudo test; or, if the clumping took place without complete loss of motion, the reaction should also be regarded with suspicion.

DR. R. C. CABOT, of Boston, followed with a

CLINICAL REPORT ON SERO-DIAGNOSIS.

He had examined the statistics of both American and foreign observers with the following results: In 1,826 cases of supposed typhoid, 1,740, or 95 per cent., autopsy confirmed the serum test. In 1,649 cases not

typhoid, 1,592, or 96 per cent., were negative. Total, 3,475 cases: 95.8 per cent. of which confirmed the serum test; two per cent. proved incorrect. In the 101 cases supposed to be typhoid, 96 had given positive reaction, while five had failed. Three of these were seen late in the disease. One was seen early in the disease and persistently gave a negative reaction, although the post-mortem examination verified the diagnosis of typhoid. In 301 cases, with diagnosis other than typhoid, 300 were negative, while one gave a positive reaction. This was a case of pernicious anemia which occurred in a negro.

The speaker had been in the habit of using dilutions of one to ten, which Dr. Welch and others had held was too strong; but his time-limit was from fifteen to thirty minutes as against two hours. He used the quick, or microscopic, method in all his examinations. The phenomena necessary to constitute a typical Widal reaction were a cessation of motion and a clumping of the bacteria. With one of these elements present and the other wanting, he would not call the case typhoid. For the purposes of statistics he had taken the first day in bed as the first day of the disease, and thought this method of calculation open to no stronger criticism than any other method of reckoning the beginning of an attack. The length of time which a patient who had once had typhoid would continue to show the reaction was *sub judice*, the longest period reported being thirteen years. Furthermore, the reaction might be intermittent. It might be present one day, absent the next, present the third day, etc.

Reference was made to the susceptibility of the blood of negroes to the test. The speaker said that Dr. Geo. B. Shattuck, of Boston, had examined the blood of seventeen negroes, and had secured positive reactions in two cases not known to have had typhoid, and in three others who had positively not had typhoid. One of these was the case of pernicious anemia previously referred to. He thought the more careful tests should be made in a laboratory, but sufficiently accurate tests could be made at the bedside by the physician with a knowledge of bacteriology. The Widal test was certainly a very material aid in the diagnosis of typhoid.

DR. BLOCH, of Baltimore, gave a clinical report on sero-diagnosis. Microscopic tests were made by diluting sixteen times. By means of the hemoglobinometer, the exact amount of dilution could be determined. Examinations made at the same time with both fresh and dried specimens showed the results to be practically the same. The earliest date on which the reaction was obtained was on the sixth day, the first day of the disease being considered as that on which symptoms compelled the patient to give up work.

One hundred and seven examinations in 46 cases of typhoid gave a percentage of failure of 6.5 per cent. The culture medium used was slightly alkaline, although experiments were made with acid and neutral media. The acid medium did not show any precipitate of dead bacteria. Especial interest attached to the use of the test in cases of tuberculosis. By this means it was possible to make a diagnosis at an early date in cases of tubercular peritonitis, tubercular meningitis, and even pulmonary tuberculosis. The author gave the history of several cases in which the diagnosis between tuberculosis and typhoid could have been made only in this way.

(To be continued.)

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JUNE 24, 1897.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
 283 WASHINGTON STREET, BOSTON, MASS.

THE LOOMIS SANITARIUM FOR CONSUMPTIVES, AT LIBERTY.

THE first annual report of the Loomis Sanitarium for Consumptives (Liberty, Sullivan Co., N. Y., with hospital and dispensary at 230 West 38th Street, New York City) has just been published.

The late Dr. Alfred L. Loomis, of whom the Sanitarium is a memorial, the report states, had pronounced views in regard to the arresting and cure of incipient phthisis by climatic treatment, and repeatedly sent patients to Colorado, the Adirondacks, and Liberty, with results proving the correctness of his views. The great distance to Colorado and the limited accommodations at Saranac made it difficult for some invalids to avail themselves of either place. Liberty then suggested itself to Dr. Loomis as an ideal situation for the erection of a sanitarium, where patients, after a four hours' journey from New York, could find themselves 2,200 feet above the sea-level, in air shown by scientific tests to be the equal of Colorado and the Adirondacks for the treatment of phthisis. The renting of a small house in West 38th Street, New York, for a city hospital and dispensary, was soon followed by the purchase of 193 acres of land two miles west of Liberty, where it was hoped in the near future to build a sanitarium. Then came the lamented death of Dr. Loomis, and, following it, the noble gift of the Sanitarium as a memorial of him by Mr. J. Pierpont Morgan.

The Sanitarium was incorporated in January, 1896, and on June 1st of the same year was opened for the reception of patients; the formal dedication of the buildings, by Bishop Potter, taking place in November. The Loomis Memorial, or Administration Building, of roughly-hewn gray stone and half-timber, is three stories in height, 190 feet long, and 60 feet wide. The house is tastefully decorated and furnished, and equipped with every modern appliance, and the grounds about it have been laid out by a skilled landscape gardener. All this is the gift of Mr. Morgan. Grouped

around the main building, and within a few hundred yards of it, are a handsome casino, for the amusement of the patients, and four cottages, all of which, with a single exception, are memorials erected by benefactors of the institution. When all the buildings are completed, by July 1st, the Sanitarium will have a capacity for seventy patients, with twelve emergency beds in addition. The laboratory is furnished with all the necessary apparatus for bacteriological and experimental work; also with a powerful x-ray apparatus and well-equipped throat-room.

The object of the Sanitarium is to help persons in the incipient stages of phthisis recover their health who, by reason of limited means, are unable to go to more expensive resorts, or to travel long distances. Only those are admitted who are in the early stages of the disease, and to whom a residence for a number of months in the Sanitarium promises either a complete cure, or such an improved condition that they can return to their homes and be able to carry on their work. The statistics at the end of the first six months show a remarkable improvement in sixty per cent. of the cases; and there have been already nine discharged in which the disease was regarded as arrested or cured.

Dr. Wm. M. Polk is the President of the Medical Board of the Sanitarium, and Dr. Henry P. Loomis, Secretary.

The sanitarium for consumptives established by Dr. V. Y. Bowditch at Sharon, Massachusetts, five or six years ago, was a pioneer in the practical application of the views and aims represented at Liberty. The Sharon Sanitarium has been less fortunate, though not less deserving of good fortune than that at Liberty. It only needs a generous endowment to fully demonstrate the benefit it is capable of affording to the class of sufferers for which it is designed.

MEDICAL NOTES.

VETO OF THE OSTEOPATHY BILL.—The Osteopathy Bill passed by the Illinois Legislature, the object of which was to legalize this peculiar form of irregular practice, has been vetoed by Governor Tanner of that State.

COMMENCEMENT AT JOHNS HOPKINS.—On June 15th, the first class to graduate from Johns Hopkins Medical School, which is now four years old, received their diplomas. The class numbered seventeen, and included one woman.

COMMENCEMENT AT RUSH MEDICAL COLLEGE. Two hundred and sixty men were graduated from Rush Medical College, Chicago, on May 26th, Commencement Day.

DR. PARK RICHTER APPOINTED DEAN.—Park Richter, M.D., has been appointed Dean of the Medical Department of the Minnesota State University. The library of the late Dean Millard is to become the property of the College of Medicine.

THE NEW BUILDINGS OF GUY'S HOSPITAL MEDICAL SCHOOL.—The new Medical School buildings of Guy's Hospital, London, were recently opened by the Prince of Wales. The Treasurer stated that nearly \$500,000 had already been received for the endowment fund of the hospital in answer to the appeal of the Prince of Wales.

A DISTINGUISHED PHYSICIAN WHO PERISHED IN THE PARIS FIRE.—Henri Feulard, M.D., a distinguished dermatologist, member of the French Dermatological Congress, and one of the editors of the *Annales de Dermatologie et de Syphiligraphie*, perished in the disaster of the Bazaar de Charité. He was forty years of age, and had already won a high reputation in his specialty. He had rescued his wife and daughter from the fire, and lost his life in endeavoring to save some others who begged for his help.

TWELFTH INTERNATIONAL MEDICAL CONGRESS.—The Executive Committee of the Congress have received from the Minister of Transportation about 7,000 free first-class tickets to Moscow and return, which will be placed at the disposition of the members of the Congress. In order to secure a free ticket each member of the Congress must inform the General Secretary of the route he will take to and from Moscow. The tickets will not be issued to the wives and families of members.

"AMERICAN JOURNAL OF INSANITY."—The *American Journal of Insanity* will hereafter be published in Baltimore by the Johns Hopkins Press. The editors will be Drs. Henry M. Hurd and E. N. Brush, of Baltimore; Dr. G. Alder Blumer, of Utica, N. Y., and Dr. J. Montgomery Mosher, of Albany, N. Y. All communications for the *Journal* should be addressed to Dr. Henry M. Hurd, care of the Johns Hopkins Hospital, Baltimore, or to any of the editors. All exchanges and business communications should be addressed to the Johns Hopkins Press, Baltimore.

FIRST INTERNATIONAL EXHIBITION OF DENTISTRY AND DENTAL-SURGERY.—An International Exhibition of Dentistry, Dental Surgery and Hygiene, will be held this year in September at the Marlborough Hall, Polytechnic Institute, Regent Street, London, W. Foreign exhibitors who are not able to attend the Exhibition, or who have no representative in London, can, if desired, be represented by the management, and have their Exhibits placed, arranged and attended to during the exhibition. All applications to be addressed to the offices of the Exhibition, 18, Hart Street, W. C.

THE JUBILEE OF ANESTHESIA IN JAPAN.—A semi-centenary festival in commemoration of the discovery of anesthesia was held at Tokio on March 4th. Addresses were delivered by Mr. J. Otsaki, on "The Relation of Foreign Languages and Medicine in Japan"; by Professor S. Sato, on "The History of the Discovery of Anesthetics"; by Dr. C. Ishiguro, on "Anesthetics in Japan"; by Dr. T. Miwa, on "Anesthetic Apparatus"; and by Prof. N. Nagai, on "The Nature

of Ether and Chloroform." A large collection of books, pictures, etc., relating to the history of medical science was exhibited. Amongst these the portraits of Simpson, Morton, and Hanaoka excited special interest.

CONTAGIOUS DISEASES IN THE BRITISH ARMY.—A women's memorial has been prepared, which is signed by Princess Christian, the Duchess of Connaught, the Duchess of Teck, and numerous other ladies. The text is as follows:

We desire to express our anxious hope that effectual measures will be taken to check the spread of contagious diseases among our soldiers, especially in India.

We appreciate and respect the opinions of those who, notwithstanding the appalling statistics to which a competent committee, appointed by the government, has recently given authority, are opposed to us on this subject. We believe that they hold, in all sincerity, that the evil of rendering vice safer and the risk of degrading women outweigh all other considerations.

But, speaking as women, we feel bound to protest against these views. We believe not only that preventive measures, if exercised with scrupulous care, do not cause any real danger to women, but that they constitute a valuable safeguard of women's virtue, and afford a great opportunity of escape from a life of vice.

We feel that it is the duty of the State, which, of necessity, collects together large numbers of unmarried men in military service, to protect them from the consequences of evils which are, in fact, unavoidable in such a community and under such conditions; and with the deepest earnestness we call on the government to do all that can be done to save innocent women and children in the present and future generations from the terrible results of vices for which they are not responsible.

THE VITALITY OF THE TURKS.—The correspondent of the *London Times* is impressed with the eagerness of the Turks to fight and with the difficulty of killing them. He mentions one man whose abdomen was penetrated by a bullet, and who not only kept his place in the ranks till the battle ended but marched ten miles afterwards. Another man with three wounds—two in the legs and one in the shoulder—continued on duty twenty-four hours until an officer noticed his condition and sent him to a hospital. "Sometimes," says the *Lancet*, "our alcoholism has been associated with our daring and our endurance as cause and effect, but here are qualities of the same sort in a non-alcoholic nation. Our contemporary's correspondent remarks further on the rapidity with which wounds heal, and says that medical men attribute it to the abstinence of the Turks. Here we should scarcely be able to match the race whose soldiers are ill-clad, ill-fed, and who take no alcoholic stimulants."

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, June 16, 1897, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 65, scarlet fever 46, measles 153, typhoid fever 5. For the week ending June 23, 1897, the following cases were reported: diphtheria 78, scarlet fever 43, measles 87, typhoid fever 6.

THE DINNER OF THE MASSACHUSETTS MEDICAL SOCIETY.—A correspondent writes us in regard to the dinner of the Massachusetts Medical Society as

follows: "It was the best arranged, best served, and best in every way I have ever been to (my record is twenty dinners during twenty-six years). The speaking seems to grow thinner every year. No doctor can fill such a big place; and I believe it is better to eat, drink and be merry, and leave the speaking for some other occasion."

DR. POLK ADDRESSES YALE MEDICAL STUDENTS.

—The Annual Address in Medicine at Yale University will be delivered on Tuesday, June 29th, by Prof. William M. Polk, M.D., of New York City, on the subject "How to Work."

A FATHER HAS A RIGHT IN HIS CHILD'S DEAD BODY.—The full bench of the Massachusetts Supreme Court recently decided, in the case of Samuel C. Burney against the Boston Children's Hospital, which was an action to recover damages for an autopsy made without the plaintiff's consent upon the body of his child, that a father has a property right in the dead body of his child before and after burial. The contention of the defendant that there is no property right in a dead body, which had been sustained by a lower court, thus apparently falls to the ground.

BIRTHDAY OF A CENTENARIAN.—Miss Hetty L. Purdy, of Derby, Conn., one hundred years old Tuesday, June 15th, was born in Rye, N. Y., June 15, 1797. At the age of eighteen, according to a report in the *Boston Transcript*, she was engaged to Dr. Seaton, a wealthy young Englishman who was studying under Dr. Bailey, of Rye. The wedding day had been set. Dr. Seaton started on a flying trip to England. He was to return on the day before the marriage. But on the trip over, his generous impulses prompted him to treat gratuitously a poor seaman who was in the throes of ship fever. The physician contracted the disease himself, and in two days died. The young girl vowed she would never wed, and, although suitors appeared, she kept her vow.

NEW YORK.

NO CONSOLIDATION OF THE NEW YORK MEDICAL SCHOOLS.—It is now definitely announced that the negotiations for the consolidation of the Bellevue Hospital Medical College and the medical department of the University of the City of New York have been finally abandoned. In consequence, the Bellevue Faculty have determined to at once begin the construction of a new building of their own. Ever since the organization of the school it has occupied a building standing within the grounds of Bellevue Hospital and belonging to the city. The lease for this structure, which was seriously damaged by fire a few months ago, expires next year, and as there were difficulties in securing a renewal of it on satisfactory terms, the Corporation decided to put up a building on land already owned by it, at the southwest corner of 26th Street and First Avenue. This land consists of six city lots immedi-

ately adjoining the Carnegie Laboratory, an important adjunct of the college, and the new medical school will be erected on three of them, with a frontage of 75 feet on First Avenue, and 125 feet on 26th Street. It will be a plain and substantial building, five stories in height, and fitted up with all the most approved modern appliances. Its cost is estimated at \$100,000, and it is hoped that it will be ready for occupancy by January 1, 1898. In the meanwhile the old building in the hospital grounds will be temporarily arranged for the work of the school, and will be used for its classes until the new one is finished. In time, if necessary, the college can extend its building by taking in the other three lots belonging to it.

THE SITE FOR THE NEW HARLEM HOSPITAL.—The Commissioners of Public Charities have selected as a site for the new Harlem Hospital (the uptown city hospital) a plot 200 by 400 feet on Lennox Avenue, between 135th and 136th Streets. For a number of years the hospital has been in an old and inadequate building on East 120th Street, and it was first intended to put up the new one on land in the vicinity, and fronting on the East River, already belonging to the city. It was found, however, that this property was not suitable for the purpose, and the site now selected will have the advantage of a much more central location, being about midway between the eastern and western districts of Harlem. The Legislature has authorized an outlay of \$300,000 for the new hospital.

YELLOW FEVER AGAIN BROUGHT TO NEW YORK.—The steamship *Advance* arrived on June 11th from Colon, with yellow fever on board. One of the second-cabin passengers died of the disease soon after the vessel reached quarantine, and another on June 13th, in the Swinburne Island Hospital.

DEATH FROM CHLORATE OF POTASH POISONING.—An inquest has just been concluded in the case of Hyman Berger, twenty-two years of age, who died in May from the effects of chlorate of potassium taken by mistake for Rochelle salts. There seemed to be little question that the drug was purchased at a pharmacy on East Broadway, but the coroner charged the jury that the evidence did not warrant them in holding any one to blame, and the latter found that the deceased "came to his death by asphyxia caused by chlorate of potash poisoning, said poison having been self-administered by mistake for salts and procured at some place unknown to the jury."

A CONVALESCENT HOME FOR NEW YORK HOSPITALS.—The Middletown Convalescent Home, under the direction of the churches of Middletown and Goshen, in Orange County, was opened early in June for the reception of convalescent children from the New York hospitals.

DEATH OF DR. E. S. BUNKER.—Dr. Edward Seaman Bunker, for many years a professor in the Long Island College Hospital, Brooklyn, died at his home at Bath Beach, L. I., on June 7th, at the age of fifty-seven.

Miscellany.

AN ANTIVIVISECTION HOSPITAL.

WE see it stated that a committee has been formed for the foundation of an antivivisection hospital from which "all vivisectors will be forever excluded." No proposition could well be sillier than this; nevertheless, we shall be glad to see the attempt made to carry it out, for its absurdity will then be all the more evident. Let us see what and whom it will be necessary to exclude in order to be logical in the determination to derive no benefit from the labors of experimental physiologists and pathologists who are here stigmatized shortly as vivisectors. First and foremost it will, of course, be necessary to exclude the Listerian treatment, and to resolve not to profit by the researches of Pasteur and Lister and the antiseptic practice which is now so universal, and has been so beneficent in its life-saving effects. Of course, all those who object to profit by the teachings of experimental physiology and pathology must at once exclude the use of the stethoscope or any of the knowledge which the experiments on respiration of living animals by Boyle, and the sounds of the valves of the heart by Hope, have brought to our aid in the treatment of heart diseases and lung disease. Properly speaking, and to be logical, no pulse should be felt, and the knowledge gained by Harvey's experiments on the heart and discovery of the nature of the circulation should be altogether kept out of view. Nitrite of amyl must, of course, not be used for the relief of angina pectoris, for that is one of the most recent conquests of physiological experiments; neither must any brain disease be localized or operations for the removal of tumors be performed, for they will be based on the knowledge gained by the researches of Ferrier and of Horsley. The use of antitoxins in the treatment of diphtheria, plague, pneumonia, erysipelas, or tetanus must, of course, be rigidly excluded. But first of all it will be necessary to find medical men of ordinary scientific standing, or, indeed, any medical men, who would willingly exclude as far as they could (for none could wholly exclude) the knowledge and methods of treatment with which so-called "vivisectors" have so richly endowed preventive and curative medicine and surgery of our day. — *British Medical Journal*.

Obituary.

DR. BENJAMIN E. COTTING.

RESOLUTIONS OF THE OBSTETRICAL SOCIETY OF BOSTON.

THE members of the Obstetrical Society of Boston wish to place on record their tribute to the memory of Dr. B. E. Cotting:

As a founder of the Society and a constant attendant at its meetings, they recall his continued interest in its objects and its welfare; they remember his loyalty to the Society in its earlier days, and that, by his efforts, it was kept alive at times when its existence seemed imperilled. They remember the ever-ready welcome at his home and his generous hospitality, the words of counsel and cheer which he gave to the younger members, the faithfulness with which he sought out and laid before us in printed form the history of the Society.

As a member of the medical profession, they refer with pride to his hearty sympathy with everything which tends

to its honor and its well-being; to the skilful services which he unweariedly put forth for our State Society and its various branches; to the impetus which he gave the organization during his presidency; services which had so marked an influence in raising and confirming its honorable position.

They cannot fail to recognize his distinguished labors in the cause of medical literature and in the support of the *Boston Medical and Surgical Journal*.

As an honored citizen and a warm, true and hearty friend, they will long miss his presence and cordially cherish his memory.

With this recognition of Dr. Cotting as a friend and a member of the profession and of the Society, they tender earnest sympathy with his family and friends in their bereavement.

Correspondence.

KOCHER'S VIEWS OF GOITRE AND CRETINISM.

PARIS, May 20, 1897.

MR. EDITOR:—In the United States familiarity with the causes of goitre, and its sequel, cretinism, is so largely theoretical and indirect, that in continuation of my last letter (p. 240), I cannot do better than give your readers some of the results of Professor Kocher's studies upon and of his researches into the origin and nature of these ailments, so frequently met in Switzerland, so rarely seen in our country.

With regard to the etiology of goitre, a matter which has been largely disputed, and concerning which many theories have been advanced, Kocher's practical inquiry began in his visit to the villages throughout the valleys and upon mountains of the Canton of Berne. He made these researches as president of a commission of twenty-five physicians. Kocher's personal share in the inquiry was very large and arduous. More than 70,000 school-children, between the ages of seven and sixteen years were passed in review; and their parentage, their antecedents, their homes, the food they ate, and especially the water they drank, were all subjected to stringent questioning and examination. This work was done with Kocher's habitual exactitude and thoroughness. As a result he formed independent opinions, the most important of which are purely original with Kocher and have been accepted as true.

The female is more frequently a victim of goitre than is the male sex. In children, between nine and fourteen years of age, goitre reaches its highest degree of frequency. While goitre sometimes, though rarely, becomes developed before children are sent to school, the position of the head in reading and writing, during school hours, probably gives a stronger tendency to the ailment, and, therefore, there exists a "school-goitre." The discovery was made that the more mature the age of the individual the greater is the development of the secondary changes in the thyroid gland. As to the time of its onset goitre usually appears near the end of the first ten years of life. Saussure asserted that if at ten years of age a child had no goitre he never would have one. Kocher found that before the seventh and eighth years goitre was an exception, but that it increased in frequency up to the thirteenth and fourteenth years.

Congenital goitre is rare. A greater exception is congenital atrophy of the thyroid gland.

In his researches throughout the Canton of Berne, Kocher discovered that those districts in which the so-called "fresh-water sandstone" prevailed were especially afflicted by goitre; on the other hand, that in districts in which "salt-water sandstone" predominated goitre was infrequent. His conclusion, however, was that the prevalence of goitre depends less upon the presence of dissimilar sandstone than upon a mixture of organic elements which, in different localities are differently prominent, and that the manner in which these varying organic peculiarities reach the people is through *drinking-water*; that neither deficient

nourishment, unhealthful dwellings nor wretchedness and poverty of every kind, are a direct causation of goitre, but that water which creates goitre is much richer in organic elements than is water which does not give rise to the affection. And yet he found that districts rich in goitre and districts which are free of the ailment are separated often merely by a valley or a river-bed. In the midst of goitre-laden localities he discovered oases in which no goitre existed. He also found that actually there existed "goitre-fountains," and that competent inhabitants were able to point out fountains whose water without exception caused goitre in the children who drank it. On the contrary, in places where goitre largely prevailed that, very often, families which had a private water-supply were free from the affection. In goitre districts the people themselves often accuse certain fountains of being a cause of the disease. When children drank water from wells, brook or river, they were largely afflicted by goitre. Long and open conductors of water are also unfavorable.

In one village Kocher found individuals who possessed normal thyroid glands and many others in whom the gland was hypertrophied. In the first case the people drank from a meadow spring, the affected drank water from a brook and fountains. In this place the cows preferred to drink from a spring which emptied into a basin, declining water from other sources. The animals which confined themselves to this spring gave more milk and were fatter and handsomer than the other cows of the village. Among goitre fountains, therefore, Kocher had discovered an exquisite anti-goitre spring, and naturally ordered an analysis of the two waters to be made. The water which caused goitre formed absolutely no deposit, and the analyst pronounced it, comparatively, a very clear drinking-water. That perfectly clear and fresh drinking-water can produce goitre is shown by the numerous cases in the valley of the Grindelwald, where the water-supply is derived from a source lying very high among the mountains.

In this examination of school-children Kocher always made a point of being perfectly clear as to what water the children used.

Reverting to the examination of the two waters: Analysis showed that while the chemical dissimilarities between them were very small, four times as much sulphate of lime existed in water which did not cause goitre as was found in water used by individuals who were affected by the tumor.

In both cases the water was fresh, crystal-clear and agreeable. The harmless water also contained twice the quantity of magnesia salts which were found in the suspected water. But, since it was found that water which was rich in lime could and did cause goitre, Kocher declines to consider these dissimilarities a sufficient explanation.

A thorough bacteriological examination of both waters was then made by Professor Tavel, of the University of Berne, with the result that in the innocuous water a far smaller number of micro-organisms was found, than in the other, namely, while in the first only nine species of cocci, bacteria and pilz, were isolated, in the other, 33 organisms were distinctly discovered. Culture of these various organisms from the two waters established the identity of only one of them. The organisms were then used *en masse* for the inoculation of guinea-pigs: in several instances there resulted a hypertrophy of the thyroid gland. A similar inoculation of dogs proved to be negative. But Kocher concludes that only by repeated experiments, especially with dogs during a long period of time, can a decision be reached. He wishes, however, to put upon record the remarkable fact that in, apparently, the cleanest and purest spring-water a large number of micro-organisms can be found. He concludes that the discovery in spring-water of this or that coccus, or of this or that bacterium, is an indication of small import, and adds that from this discovery it is absolutely impossible to draw the slightest conclusion.

Finally, he says, that a certain peculiarity of geological formation has an influence in the development of goitre, but that it is equally true that it is not the mineralogical

formation of ground, not the coarse chemical quality of underlying rocks, which produces the affection, but rather a mixture or uncleanness which taints the drinking-water as it filters through the underlying strata. As a theory, it may be supposed that certain geological combinations probably filter water and render it harmless, while others allow the passage of matter, which injures the thyroid gland of individuals who drink water of the latter origin. Last year, Baumann, late professor of chemistry in Freiburg, announced the discovery, in the normal thyroid gland, of iodine in the proportion of one milligramme of iodine to one gramme of the gland. In a struma he found little or no iodine. This absence of iodine is exciting attention as a possible, if not probable, cause of goitre. In combination the substance is called *thyroidine* or *iodothyroïne*, and is being artificially compounded and given to goitre cases in hope of relieving the ailment.

CRETINISM.

With regard to Cretinism, Kocher, touching the results of heredity, finds in sound and strong parents, who have lived far from regions in which cretinism is endemic and had there begotten normal children, that, after moving into a district of cretinism, they have begotten one or more cretins. In some of these cases the parents, either father, mother, or both, became victims of goitre, but without a trace of cretinism. Moreover, after such parents have returned to their former place of residence, they again begot healthy children. In some cases normal children were begotten in the cretin districts by parents to whom cretins were also born.

Various theories have attempted explanation of the foregoing facts. The most reasonable of these is that the same influences which lead to goitre are a cause of cretinism, or, that goitre is a stepping-stone to cretinism, and, where it is widespread, that cretinism always exists where goitre is endemic.

Kocher's opinion is that whenever goitre or cretinism appears in children, one or the other of the parents will be found to have goitre. He strongly asserts that the discomforts caused by goitre, no matter how intense they may be, never lead directly to cretinism, not even in its slightest degree, but that cretinism arises only and solely, when, by degeneration of the thyroid gland through goitre, or equally well by means of some other injury of the gland, its function is destroyed or seriously impaired. Or, quoting from Morel: "Goitre is the first stage of the road which leads to cretinism."

So long ago as 1830, Troxler said that the thyroid gland exerts an influence upon psychical life, the importance of which influence is not sufficiently understood.

Kocher was the first to take the stand that in operating upon goitre: (1) That total extirpation of the gland was not only wrong, but that it surely would lead to psychic disturbance, to cretinism, or, at any rate, to a greater or less disturbance of the general well-being. (2) That these disturbances cause a characteristic form of illness to which Kocher gave the name of "*Cachexia strumipriva*," which term, later, he modified into "*Cachexia thyropriva*," which he considered a truer expression of the ailment. (3) That in young individuals this condition exhibits a great similarity to cretinism, and, therefore, that there exists a decided dependence between cretinism and the thyroid gland. (4) That the total extirpation of the thyroid gland is wholly unallowable.

These assertions were first made before the Congress of Surgeons in Berlin. They were wholly new and awaited and were received with a large degree of sarcasm. Later, Reverdin, the elder, of Geneva, to whom in conversation Kocher had previously mentioned these conclusions, made a thorough examination of them with reference to patients from whom he had extirpated the entire thyroid gland. He acknowledged the truth of Kocher's discovery in a paper, which, later, he read before the French Congress of Surgeons, but did so, not only without mentioning Kocher's priority in the matter, but allowed himself to be recognized as the author of the new gospel.

He was rewarded with the cross of the Legion of Honor. Kocher's recompense was the decided assumption on the part of the German writers who had derided his original announcement of the facts in question, and who did not trouble themselves to look into the matter, that Reverdin was the first to recognize and describe the cachexia thyreopriva. In various pamphlets, professional friends of Kocher's have shown the facts in their true light, bitterly denouncing Reverdin and leaving him in an unenviable position. Kocher himself has done nothing but give a simple statement of the affair, in passing, in his pamphlet on cretinism.

To return to the subject under consideration. Kocher says so long as sound glandular substance remains, that the thyroid gland has nothing to do with cretinism. Goitre is dangerous only when it causes destruction of the gland, and, in consequence, abolishes its function. This danger can be averted by operation. In spite of this, a few professional teachers still advise against the removal of the goitre.

Kocher is very decided in his opinions with reference to myxedema. Inasmuch as it represents merely a certain stage of the affection to which he finally gave the name of cachexia thyreopriva, he considers the term myxedema confusing and imperfect. It originated with reference to a change in the skin, and represents simply the stage of thickening and hard infiltrating of the skin, these conditions being derived from an increased deposit of mucoid matter in the cellular tissue.

The English Myxedema Commission pronounced its decision almost wholly from adult cases; but Kocher has found that typical, so-called myxedema appears in children. On the other hand, that cachexia thyreopriva is a constant consequence of the removal of the whole of the thyroid gland. So far as etiology is concerned, his conclusion is that myxedema cachexia thyreopriva and cretinism are identical. And, the Myxedema Commission having concluded that "atrophy of the thyroid glands, which formerly was not remarked, is an unfailing pathologico-anatomical accompaniment of myxedema, Kocher says this means neither more nor less, so far as origin is concerned, than that myxedema and cachexia thyreopriva are identical diseases. Since Kocher has found that in any form of so-called myxedema, the cause of constitutional disturbance is, through metastasis, in the thyroid gland, he advises in all cases of myxedema, that the antecedents of the patient, especially as to drinking-water, dwelling-place, place of birth and family relations, should be carefully analyzed. It is, however, distinctly known that cretinism is connected neither with absence nor presence of a goitre, but that it is directly dependent upon cessation of function in the thyroid gland, which may occur either through inflammation or removal of the gland on account of malignant disease.

While congenital goitre is an exception and congenital atrophy of the thyroid gland a still greater variety, cases are known, as has already been pointed out, in which, after reaching a district rich in goitre, perfectly sound parents can beget cretins.

Through the maternal blood the fetus absorbs the abnormal influence into its thyroid gland, and in consequence of early and intense disease of the gland, atrophy supervenes. Nevertheless, the thyroid gland of the mother is not necessarily involved, for adults possess far less sensibility to the influences which lead to goitre than is the case in earlier years. The conclusion is that inherited and, at the same time, congenital cretinism is derived from the mother alone; while inherited cretinism, which appears only after a lapse of months, or years, is derived from the father alone.

Inherited and congenital cretinism is an exception. It not only implies a mother who has had goitre but also a mother who is affected by cretinism, that is, atrophy of the thyroid gland. Inherited, but not congenital, cretinism implies a father who is a cretin and a relatively normal mother. But, in the first case, the child may have inherited from the healthy parent a well-developed thyroid gland (or one sufficiently well-developed), which, after

birth, begins its function and thus disposes of all signs of congenital cretinism.

But by far the most frequent form of cretinism is congenital and not inherited. According to Kocher, the so-called inherited cretinism, as a rule, is congenital, that is, acquired during fetal life. The injury of the thyroid gland and the pathologico-anatomical substratum are the same as in cretinism which develops later. But the injurious material is absorbed by the mother from without, and by her is transferred to the thyroid gland of the fetus. The overruling factor, then, is always the influence of the land upon which the mother lives. So long as the child is in embryo, its tissues, the provision and nourishment, as well as the disposal of waste products are cared for through the maternal blood. If, therefore, the thyroid gland of the child does not develop, or becomes atrophied through disease, the gland of the mother acts perfectly, both for herself and the child. It is, then, evident that the body of the child, at the moment of birth, will not show any more cretinic degeneration than that of the mother herself. If the latter have only a goitre in a thyroid gland in a normal portion of which the functions are still satisfactory, the child, at birth will be plump and well-shaped. This is taught by experience. It is only when the child, independently of the mother, begins to nourish its own nervous system and with it the thyroid gland, that, as in acquired cretinism, the disturbance begins gradually to appear.

When Kocher says that in the strict sense of the term, cretinism is not congenital, and yet also says, that the most frequent form of cretinism is congenital, he may seem inconsistent; but he is not. He means simply that while children are not born cretins the thyroid gland in the majority of cretins has been *congenitally* so influenced that as the child grows the sleeping abnormality in the gland begins to develop and the process continues until cretinism has become established. As can be seen, this is not strictly congenital, that is, the condition does not appear at birth and yet it is congenital, because, during fetal life, through the blood, or nourishment, or drinking-water, or the mother, who herself may not have been a cretin and may have possessed a normal thyroid gland, the injurious tendencies were implanted in the thyroid gland of the fetus.

After a total excision of the thyroid gland the following symptoms soon begin to appear: oppression, fatigue, weakness and a sense of weight in the limbs. Fatigue frequently precedes pain in the arms, legs, neck and shoulders. There is a stiffness of the extremities, especially of the arms; a feeling of coldness supervenes. All these symptoms go hand-in-hand with a commencement of psychic disturbance. Thought is slow, so also are reactions. The patient is not actually stupid. He experiences rather, a feeling of difficulty in the use of the sensitive motor and sensory apparatus and is vexed by it. A swelling of various localities begins—of the eyelids, nose, lips, feet, hands and abdomen. The hair becomes rough and thin, the mucous membrane swells; anemia appears, breathing capacity diminishes; yet with all these symptoms there may exist a perfect power of judgment. Later, mental disturbances and epileptic attacks set in. This condition is cachexia thyreopriva and not myxedema.

Believing that drinking-water is the cause of goitre and secondarily of cretinism, and after proposing various means of procuring pure and safe water, Kocher says: "If they prove impossible then nothing remains but to do as surgeons—and the Chinese—do: *boil the water*. We look with proud contempt upon the tail-wearers of the heavenly land, but this time we wear the cue. The Chinese cannot comprehend why these barbarians of the sunset land drink raw water; and I, also, fail to understand it. To eat most of our food in a raw state would disgust us and yet, undoubtedly, we poison ourselves daily by drinking raw water. Between water as a beverage and bathing-water should be drawn a heavier line than has yet been done."

Yours respectfully,

H. O.

METEOROLOGICAL RECORD

For the week ending June 12th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Amesbury	10,320	—	—	—	—	—	—	—

Deaths reported 3,356; under five years of age 898; principal infectious diseases (small pox, measles, diphtheria and croup, whooping cough, erysipelas, diarrheal diseases and fever) 367, consumption 28, acute lung diseases 312, diphtheria and croup 141, diarrheal diseases 84, scarlet fever 40, typhoid fever 28, measles 24, cerebro-spinal meningitis 17, erysipelas 10, small-pox (New York) 1.

From typhoid fever Chicago 7, Philadelphia 5, St. Louis 4, New York 2, Brooklyn, Baltimore, Boston, Cleveland, Washington, Pittsburg, Nashville, Worcester, Lawrence and Malden 1 each. From measles New York 10, Brooklyn 6, Boston 3, Chicago and Philadelphia 2 each, Pittsburg 1. From cerebro-spinal meningitis Boston 8, New York 5, Somerville 2, Washington and

Newton 1 each. From erysipelas New York 3, Chicago 2, Philadelphia, Boston, Washington and Providence 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,992,524, for the week ending June 5th, the death-rate was 17.4. Deaths reported 3,661; acute diseases of the respiratory organs (London) 229, measles 121, diphtheria 56, diarrhea 34, scarlet fever 32, fever 26.

The death-rates ranged from 12.0 in Brighton to 27.1 in Salford; Birmingham 20.2, Bolton 24.9, Croydon 13.8, Gateshead 18.1, Huddersfield 17.0, Leicester 18.4, Liverpool 23.1, London 15.4, Manchester 21.9, Newcastle-on-Tyne 15.8, Nottingham 13.1, Portsmouth 13.4, Sheffield 23.3, Swansea 17.2.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 12, 1897, TO JUNE 18, 1897.

Leave of absence for one month, on surgeon's certificate of disability, with permission to apply for an extension of one month, is granted MAJOR WILLIAM C. SHANNON, surgeon, U. S. Army, Jackson Barracks, La.

Leave of absence for one month, to take effect about July 24, 1897, is granted CAPTAIN WILLIAM F. LIPPITT, JR., assistant surgeon, Fort Leavenworth, Kan.

Leave of absence for one month, with permission to apply for an extension of one month, to take effect upon his relief from duty at Fort Robinson, Neb., is granted FIRST-LIEUT. CHARLES LYNCH, assistant surgeon.

Leave of absence for four months, on surgeon's certificate of disability, is granted FIRST-LIEUT. BENJAMIN BROOKE, assistant surgeon, Fort Thomas, Ky.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JUNE 12, 1897.

M. H. SIMONS, surgeon, ordered to the "Iowa," June 16th.

WASHINGTON B. GROVE, commissioned assistant surgeon from June 3d.

R. P. CHANDALL, passed assistant surgeon, detached from Naval Hospital, Norfolk, June 14th, and ordered to the "Iowa," June 16th.

W. G. FARWELL, medical inspector, detached from special duty, Marine Rendezvous, Philadelphia, and continue other special duty.

D. O. LEWIS, surgeon, after completion of examining board, Naval Academy, ordered to the Marine Rendezvous, Philadelphia.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE TWO WEEKS ENDING JUNE 12, 1897.

GREENE, JOS. B., assistant surgeon. To rejoin station, Detroit, Mich., on return to Evansville, Ind., of Passed Assistant Surgeon, P. M. CARRINGTON. June 9, 1897.

GRUBBS, S. B., assistant surgeon. To proceed to Boston, Mass., and report to medical officer in command of Service for duty, on return to Detroit, Mich., of Assistant Surgeon, JOS. B. GREENE. June 9, 1897.

HASTINGS, HILL, assistant surgeon. Granted leave of absence for seven days from June 7, 1897. Leave of absence extended for seven days from June 14, 1897.

RECENT DEATHS.

JOSEPH JACKSON BOYNTON, M.D., M.M.S.S., died in South Framingham, June 17, 1897, aged sixty-four years.

DR. JOEL W. SMITH, of Charles City, Io., who died there recently, at the age of seventy-two years, was a successful practitioner who had won in large degree the respect and confidence of the community in which he practised. He was born in 1824 in Franklin, N. Y., and graduated from the Yale Medical School in 1850, and subsequently became a pupil of Dr. William Detmold, of New York City. He practised for a short time in New York State, but in 1857 removed to Charles City, Io., which was the scene of his labors until his death. He was a member of the American Medical Association, of the Iowa State Medical Society, being vice-president in 1872; of the International Medical Congress, Philadelphia, 1876, and Washington, 1887; of the American Public Health Association, of the Iowa Public Health Association and of the American Association for the Advancement of Science. His wife, a daughter and three sons survive him.

WRIGHT, JAS. HOMER, A.M., M.D.

INDEX TO VOLUME CXXXVII.

- Abbott, C. S.** Some obstinate forms of eczema, 373.
- Abbott, S. W.** Consumption as an indoor disease, 524.
- Abdomen.** Pistol-shot wounds of the abdomen, Beach, H. H. A., 368.
- Abdominal Surgery.** Three cases of abdominal stab-wound, laparotomy in each case, with recovery, Meigs, J. V., 597.
- Abuse of Medical Charity.** Medical responsibility of medical charity, Rhoades, J. H., 430; supplementary report to the Society of the County of New York by its committee on the abuses of medical charity, 558; abuses of medical charity, 665.
- Aconite.** A case of aconite poisoning, Greenleaf, R. W., 57.
- Actinomycosis hominis.** Ruhräh, J., 639.
- Addison's Disease** and pneumothorax, Shattuck, F. C., 624.
- Alcohol.** Narcotism and alcoholism, 452; sudden death due to alcoholism, Hurd, E. P., 619.
- Allen, C. W.** A scale of measurements for the accurate and uniform description of cutaneous lesions, 446.
- Allen, G. W.** Report of a case of hernia testis, 64.
- Anatomy.** A sexual study of the size of the articular surfaces of the long bones in aboriginal American skeletons, Dorsey, G. A., 80; a rare form of occipito-atlantal articulation, Dorsey, G. A., 204.
- Anemia.** Taylor, A. E., 42.
- Anesthesia.** Chloroform in obstetrics, Davis, E. P., 193, 205; the superiority of chloroform as an anesthetic in midwifery practice, Worcester, A., 196, 205; the use of ether in obstetric practice, Green, C. M., 198, 205; ether and chloroform, 215; statistics of anesthesia, 219; the prevention of pneumonia following anesthesia, Whitney, W. F., 311, 316; chloroform and ether, Keefe, D. E., 641; the relative safety of chloroform and ether, 660.
- Annus Medicus.** 679.
- Antitoxin** as a prophylactic, Twombly, E. L., 649.
- Aphorisms.** 506.
- Appendicitis.** Recent foreign literature on appendicitis, 91.
- Arequipa.** A visit to the highest meteorological station in the world, Ward, R. DeC., 637.
- Army.** An army medical board, 45.
- Art.** The human foot in art, Bradford, E. H., 305.
- Arthritis deformans.** Stewart, J., 269.
- Anatlin, H. W.** The bill for a department of public health, 559.
- Autopsies.** Carpenter, I. L., 374.
- Ayres, S.** Uncommon nasal parasthetic stenosis, 378.
- Babcock, R. H.** A brief consideration of some points in the management of consumption, 88.
- Bacillus.** A possible aid to the discovery of the tubercle bacillus in the urine, Bryson, J. P., 64; yellow fever and the bacillus icteroides, Sanarelli, C., 93; the bacillus icteroides, 116.
- Bacteriology** run mad, 355.
- Baker, S.** Steps toward insanity, 378.
- Bancroft, C. T.** Two cases of homicidal aponesic, transitory frenzy, 385.
- Bangs, L. B.** Results after nephrectomy for renal tuberculosis, 39.
- Barber shop.** The barber shop as a menace to the public health, Sutter, A. W., 823.
- Barney, C. N.** Cerebral syphilis, with report of a case of chronic meningo-encephalitis secondary to syphilis, 671, 677.
- Bartlett, E. J.** An examination of forty-three published cases of opium or morphine poisoning, 674.
- Baxter, W. B.** The use of tincture of iodine in chronic trachoma and pannus, 417.
- Beach, H. H. A.** Cancer of kidney, nephrectomy, 13; pistol-shot wounds of the abdomen, 368; chronic hydrocephalus—puncture, 676.
- Bed.** Death from collapse of a folding bed, 247.
- Bellevue** Hospital Medical College, laying of the corner-stone, 529.
- Beri-Beri** at the Richmond Asylum, Dublin, 164.
- Berlin.** International Congress of Leprosy, 478; Berlin letter, 665.
- Bibliography.** Abbott, A. C., the principles of bacteriology, 115; Albitt, F. C., a system of medicine, 500; American Journal of Physiology, 451; Andrews, G. F., the living substances as such and as an organism, 525; Bishop, S. S., diseases of the ear, nose and throat and their accessory cavities, 579; Butler-Smythe, A. C., a first series of fifty-four consecutive ovariotomies, with fifty-three recoveries, 398; Cadfield, W. B., practical notes on urinary analysis, 186; Dakin, W. R., a handbook of midwifery, 660; Delangdale, E., congenital dislocation of the femur, 378; Eccles, W. M., elementary anatomy and surgery for nurses, 322; Fick, A. E., diseases of the eye and ophthalmoscopy, 632; Fuertes, J. H., water and public health, 500; Garrigues, H. J., a text book of the diseases of women, 604; Hare, H. A., practical diagnosis, 679; Herold, J., a manual of legal medicine, 632; Hill, L., the physiology and pathology of the cerebral circulation, 632; Hinsdale, G., syringomyelia, 398; Holt, L. E., the diseases of infancy and childhood, 449; Hubbard, S. C., biographical sketch of the life and writings of the late Prof. Henry Bronson, M.D., 138; Jellett, H., a short practice of midwifery, 214; Jewett, C., the essentials of obstetrics, 554; Mallory, F. B., pathological technique, 525; Mason, W. P., water-supply considered principally from a sanitary standpoint, 500; Massachusetts, the twenty-eighth annual report of the Massachusetts State Board of Health, 661; Martin de Argenta, D. C., las inflamaciones pelvianas de la mujer, y su tratamiento mas inteligente segun las clinicas, 399; Medical News visiting list for 1898, 604; Mitchell, S. W., clinical lessons on nervous diseases, 399; Morris, R. T., lectures on appendicitis and notes on other subjects, 214; Mynter, H., appendicitis and its surgical treatment, 659; Navy, annual report of the surgeon-general of the United States Navy, 662; Norris, W. F., and Oliver, W. A., system of diseases of the eye, 65; Packard, H., five years' work in surgery, 322; Park, R., a treatise on surgery, 321; physicians' visiting list, 632; Pozzi, S., a treatise on gynecology, medical and surgical, 632; Preston, G. J., hysteria and certain allied conditions, 499; Pye, W., elementary bandaging and surgical dressing, 186; Rensen, I., the principles of theoretical chemistry, with special reference to the constitution of chemical compounds, 322; Richardson, B. W., vita medica, 632; Rideal, S., water and its purification, 500; Schäfer, E. A., a course in practical histology, 400; Senn, N., tuberculosis of the genito-urinary organs, 631; Simon, C. E., Simon's clinical diagnosis, 660; Smith, J. G., abdominal surgery, 115; Snell, E. H., compressed air illness; or, so-called caisson disease, 500; Solly, S. E., a handbook of medical climatology, 450; Stewart, G. N., a manual of physiology with practical exercises, 322; Stockham, A. B., Karezza, ethics of marriage, 579; Taylor, R. W., sexual disorders of the male and female, 659; Thompson, J. A., a contribution to the history of leprosy in Australia, 473; Thorington, J., retinoscopy (or shadow test) in the determination of refraction at one metre distance with the plane mirror, 138; Vaughan, V. C., and Novy, F. G., ptomaines, leucamines, toxins and antitoxins; or the chemical factors in the causation of disease, 18; Vessey, C. A., ophthalmic operations as practised on animals' eyes, 399; Wharton, H. R., minor surgery and bandaging, 186; Wise, P. M., a text book for training schools for nurses, 659.
- Bicycle.** The bicycle again, Shadwell, 117.
- Billroth** and Pir golf, Rovinsky, A., 666.
- Biography.** Allen, H., 532, 610; Avery, C. H., 504; Bates, N. L., 432; Bloodgood, W. E., 430; Boer, O., 168; Bolles, J. C., 304; Bradbury, O. N., 297; Bratton, W. D., 432; Bucknell, J., 168; Chapman, F. B., 640; Clark, C. E., 640; Culver, J. E., 506; Daly, J. P., 430; Dana, W. L., 297; Davis, C. H., 328; Duchenne, 382; Evans, T. W., 532; Foster, T. A., 297; Fresenius, C. R., 92; Frye, P. G., 403; Fuller, A. J., 297; Garcean, T., 663, 668; Gilchrist, W. N., 609; Hayes, T. J., 248; Hays, D., 326; Heidenhain, R. P. H., 456; Hicks, J. B., 328; Higgins, A., 403; Hitchcock, F. E., 297; Hoitt, G. C., 640; Holmgren, A. F., 384; Hutton, W. H. H., 45; Jones, J. G., 477; Krog, A. E. W., 189; Lindsley, J. B., 640; Love, J. J. H., 142; Lusk, W. T., 67; Luys, J. B., 304; McCormick, R., 167; Meyer, V., 220; Moody, D., 297; Moore, I. L., 384; Morrison, R. B., 408; Oertel, M. J., 168; Olmstead, J., 609; Pirogoff, N. I., 604; Read, I. B., 69; Rendell, J., 327; Ritter von Leich, J., 168; Robitaille, O., 263; Sanger, E. F., 167; Simpson, J., 456; Skilton, J. A., 581; Smith, R., 452; Stearns, I. H., 304; Tarnier, 668; Thayer, W. H., 692; Thompson, E., 640; Thurman, W. M., 117; Van Havenberg, J. O., 637; Webster, J. O., 297; Welch, E. A., 612; West, G. W., 163; Wey, W. C., 44.
- Blake, C. J.** Intra-tympanic disease as a factor in the causation of aural vertigo, 5, 14; the fatigue of deafness, 174.
- Blake, J. B.** Palliative and operative treatment of fistula in ano, 230.
- Blodgett, A. N.** Entire destruction of the soft palate and velum by syphilis, 133, 135.
- Boland, E. S.** A caution against the use of antefebriin on extensively blistered surfaces, 65.
- Bombay.** High mortality at Bombay, 247.
- Bonney, S. G.** Observations upon pulmonary tuberculosis in Colorado, 39, 282; what inferences may be drawn from cases of pulmonary tuberculosis reported to have originated in Colorado? 362.
- Borland, E. B.** Curability of pulmonary tuberculosis, 40.
- Bowen, J. T.** Report on dermatology, 395.

- Brackets, E. G. Treatment of torticollis, 137.
- Bradford, E. H. A study in human gait, 162; round shoulders, 257; the human foot in art, 305; an examination of human gait, 329.
- Brannan, J. W. Address before the Harvard Medical Alumni Association, 266.
- Brewer, G. E. Some observations upon the surgical anatomy of the kidney, 38.
- British medicine in Greater Britain, 221.
- Brower, D. R. Climate in relation to the nervous system, 114.
- Brown, S. Diseases of the nervous system affected by climate, 90.
- Brunner, Starvation of the reconcentrados in Cuba, 478.
- Bryan, J. H. Intra-nasal tumor, 185; report of a case of suppurative inflammation of frontal, ethmoidal and maxillary sinuses, 186.
- Bryson, J. P. Clinical observations on loose and displaced kidney, 38; a possible aid to the discovery of the tubercle bacillus in the urine, 64.
- Burr, C. R. The tuberculous diathesis, 542, 563.
- Burridge, W. L. A case of ovariectomy during pregnancy, 104, 108; a case of emansio mensium, or absolute amenorrhea in a married woman twenty six years old, 393, 398; division of the utero-sacral ligaments and suspensio uteri for immobility retroposition with ante-flexion, 622.
- Burrell, H. L., and Cushing, H. W. Report on surgery, 154, 178; recent progress in surgery, 312.
- Cabot, A. T. Chondro-sarcoma of the femur, 161; science in medicine, 481; points in operative technique, 492.
- Cabot, R. C. Health boards and the Widal test for typhoid fever, 276; alcoholic stimulation in continued fevers, 573; the diagnosis of trichinosis, 676, 678.
- Cesarean Section. A case of Cesarean section, Reynolds, E., 35.
- Caculi. Cholelithiasis, Hunter, W., 350; the symptoms and diagnosis of cholelithiasis, Graham, 351.
- Calculus. Gall-stones formed on the sutures of an operation for cholecystotomy twenty years ago, Homans, J., 13; a case of cystin calculus in the male bladder, Thordike, P., 49; recurrent stone in the bladder of a child, Judkins, W., 64; a case of renal stone, Reynolds, E., 398.
- Call, E. L. Acute tuberculosis in puerperal women, 342, 350.
- Campbell, D. S. The treatment of croupous pneumonia, 41.

- Carpenter, I. L. Autopsies, 374.
- Carville, H. DeW. Glaucoma, 372.
- Cassellberry. Discussion on atrophic rhinitis, 211.
- Cellular Nucleus. Has the cellular nucleus independent existence? 373.
- Centrevall, I. A. A case of moon-blindness, 383.
- Chamberlain, C. N. Winter Park, Florida, as a winter resort, 667.
- Channing, W. Characteristics of insanity, 585, 613.
- Cheever, D. W. The new surgery, 1; address before the Harvard Medical Alumni Association, 268.
- Cheney, F. E. Penetrating wounds of the chest, 49.
- Chest. Penetrating wounds of the chest, Cheney, F. E., 49.
- Children. Report on diseases of children, Rotch, T. M., and Wentworth, A. H., 105, 650; a case of gastric ulcer in a child four months old, Hibbard, C. M., 177; gastric ulcer in the new-born, Lincoln, J. R., 178.
- Chiamore, G. A new method of removing polypoid growths from the bladder, 64.
- Chloroform in obstetrics, Davis, E. P., 193, 205; the superiority of chloroform as an anesthetic in midwifery practice, Worcester, A., 196, 205; chloroform and ether, Keefe, D. E., 641; the relative safety of chloroform and ether, 669.
- Cholecystitis. A case of cholecystitis due to the typhoid bacillus, Richardson, M. W., 570.
- Cholecystotomy. Two cases of cholecystotomy, Kidder, E. H., 361.
- Cholelithiasis, Hunter, W., 350; the symptoms and diagnosis of cholelithiasis, Graham, 351.
- Circulatory System. Pericarditis, some points in its diagnosis and treatment, Shattuck, F. C., 28; anemia, Taylor, A. E., 42; a case of ligature of the innominate artery for aneurism, Gay, G. W., 73, 87; penetrating wound of the heart, recovery, Parrozzani, 190; on the proper use of terms to denote myocardial changes, Tyson, J., 270; an autopsy in a case of innominate aneurism cured by the introduction of gold wire and electrolysis, 275; a case of ruptured aorta, Mallory, 315; phlebotomy, Leet, J. A., 373; a sign of cardiac failure, Jackson, H., 467, 473; report on progress in thoracic diseases, Sears, G. G., 471; three cases of congenital heart disease, Townsend, C. W., 493; two cases of aortic regurgitation and tabes dorsalis, Vickery, H. F., 498; the "skin heart" as a factor in the human circulation, with special reference to the Brand and Schott treatment, Hutchinson, W., 511.
- Clark, L. P. Report of a case of asthmatic paroxysms taking the place of epileptic fits, 622.
- Climate. Some personal observations of the effects of changes of climate upon men and animals, Newton, R. C., 112; renal diseases as affected by climate, Danforth, I. N., 114; climate in relation to the nervous system, Brower, D. R., 114.
- Cobb, F. C. A new electrical nasal saw, 520; acute inflammation of the antrum of Highmore, 594, 603.
- "Cock-matrons," 191.
- Coe, F. H. Medical laws of the State of Washington, 559.
- Collins, J. The pathology and morbid anatomy of Huntington's chorea, with remarks on the development and treatment of the disease, 657.
- Congress. The German Congress für innere medicin, 70; Twelfth International Medical Congress, Jacobi, A., 94.
- Constipation. Treatment of constipation, Pfaff, F., 256.
- Coolidge, A., Jr. Hysterical dysphagia, 185; recent progress in laryngology, 598.
- Coxes, W. P. A case of diphtheria of the vulva, 470.
- Cowles, E. The relation of mental diseases to general medicine, 277, 297.
- Crichton-Browne, J. Brain denudate, 664.
- Cuba. Starvation of the reconcentrados in Cuba, Brunner, 478.
- Cumston, C. G. The accidents produced in sero-therapeutics, 23; specimens, 318; a case for diagnosis, 469.
- Cushing, E. W. Gonorrhea in women, 240; pathological specimens, 245.
- Cutaneous System. Some obstinate forms of eczema, Abbott, C. S., 373; report on dermatology, Bowen, J. T., 365; address before the American Dermatological Association, White, J. C., 422; a contribution to the study of bleeding stigmata, Hyde, J. N., 423; hysterical dermatoneuroses, Van Harlingen, A., 423; linear nevus, Morrow, P. A., 423; the various forms of pityriasis and their relations to erythema, eczema and psoriasis, Fox, G. H., 423; a discussion upon the x-rays, Gilchrist, 423; strong solutions of the ichthyol group in acute and chronic inflammatory conditions of the skin, Klotz, G. H., 424; the nature of the xanthomata, Politzer, S., 424; contributions to the etiology of congenital ichthyosis, Winfield, G. M., 425; hereditary and continuous shedding of the finger-nails, Montgomery, D. X., 425; symmetrical atrophy of the skin, Fordyce, J. A., 425; some cases of feigned eruption, Shepherd, F. J., 426; eleven cases of porokeratosis (Albelle) or hyperkeratosis excruciatia (Respighi) in one family, Gilchrist, T. C., 445; a scale of measurements for the accurate and uniform description of cutaneous lesions, Allen, C. W., 446; a peculiar affection of the hair follicle, Grindon, J., 446; impetigo herpetiformis, Hartzell, M. B., 446; impetigo herpetiformis or dermatitis herpetiformis, Fordyce, J. A., 446; pseudo-lupus of the face due to the presence and growth of blastomycetes or budding organisms resembling yeast plant, Gilchrist, T. C., 447; lymphangiomata of the labia majora, White, J. C., 447; International Congress of Leprology, letter from Berlin, 478; a new affection, White, J. C., 491; two unusual cases of skin disease, White, J. C., 623; multiple lipoma of the skin, cystic adenoma of sebaceous glands, Porter, C. B., 625.
- Cutler, E. G. General remarks upon gastric dyspepsia, 249; record of two cases of beginning pulmonary tuberculosis treated with subcutaneous injections of Koch's tuberculin T. R., 571, 577.
- Cutler, E. G., and Elliot, J. W. Chronic ulcer of the stomach, 54, 60.
- Cystitis. Some cases of cystitis in women, 97, 109, 126.
- Da Costa, J. M. The scholar in medicine, 229.
- Daly, W. F. Purulent ophthalmia from the bacteriological standpoint, 131.
- Dana, C. L. A consideration of the paresthetic neuroses, psychroesthesia and kaumesthesia, 654.
- Dane, J. A new modification of the hip-splint, 59; some effects upon the leg of pronation of the foot, 138.
- Danforth, I. N. Renal diseases as affected by climate, 114.

- Diabetes. On the dietetic treatment of diabetes, Sandby, R., 270; the treatment of diabetes by uranium nitrate, Duncan, E., 271.
- Diagnosis. A case for diagnosis, 469.
- Digestive System. Chronic ulcer of the stomach, Cutler, E. G., and Elliot, J. W., 54; urethro-rectal fistula, Tuttle, J. P., 61; recent foreign literature on appendicitis, 91; a report of three cases of cancer of the stomach in which hydrochloric acid was found, Vickery, H. F., 132, 136; the radical cure of inguinal hernia by injections of chloride of zinc, 163; ruptures of the viscera and their connection with surgical shock, Dwight, E. W., 171, 182, 202; a case of gastric ulcer in a child four months old, Hibbard, C. M., 177; gastric ulcer in the new-born, Lincoln, J. R., 178; hysterical dysphagia, Coolidge, A., Jr., 185; palliative and operative treatment of fistula in ano, Blake, J. B., 230; general remarks upon gastric dyspepsia, Cutler, E. G., 249; treatment of constipation, Pfaff, F., 256; on the dietetic treatment of diabetes, Sandby, R., 270; the treatment of diabetes by uranium nitrate, Duncan, E., 271; enteroptosis as a clinical factor in the diseases of women, Stone, A. K., 332, 348; movable kidney and enteroptosis, Luod, F. B., 335, 346; enteroptosis, Dole, M. P., 345; mucous colitis, Palmer, H., 372; foreign bodies in the alimentary canal in children, Woodman, M. S., 372; the surgery of the stomach, 400; perforation of a gastric ulcer into the pericardium, 404; my experience with hyperacidity, Liebmann, G., 465; digestion leucocytosis as an aid in diagnosis of cancer of the stomach, Capps, J. A., 468; intestinal obstruction from band, Porter, C. B., 494; a new method for the radical cure of inguinal hernia, 526; the chemical examination of the gastric contents, Hewes, H. F., 535, 565.
- Diphtheria. Two remarkable recoveries from malignant diphtheria, Judd, L. D., 113; a case of diphtheria of the vulva, Coe, W. P., 470; antitoxin as a prophylactic, Twombly, E. L., 649.
- Disinfectants, Robinson, F. C., 523.
- Dispensary. A new dispensary abuse, 45; the results of a year's endeavor to lessen the dispensary abuse at the Rhode Island Hospital, Providence, 69; an effort to correct medical charity abuses, 118; Boston Dispensary, 463.
- Dole, M. P. Enteroptosis, 345.
- Dolichocephaly and tuberculosis, 20.
- Dorsey, G. A. A sexual study of the size of the articular surfaces of the long bones in aboriginal American skeletons, 80; a rare form of occipito-atlantal articulation, 294.
- Dulles, C. W. Consumption not contagious, 236.
- Duncan, E. The treatment of diabetes by uranium nitrate, 271.
- Dupuytren. The etiology of Dupuytren's contraction of the palmar fascia, 581.
- Dwight, E. W. Ruptures of the viscera and their connection with surgical shock, 171, 182, 202.
- Dyspepsia. General remarks upon gastric dyspepsia, Cutler, E. G., 249; treatment of constipation, Pfaff, F., 256.
- Ear. Intra-tympanic disease as a factor in the causation of aural vertigo, Blake, C. J., 5, 14; some of the general principles which should govern operations for otitic brain disease, 145; the fatigue of

- deafness, Blake, C. J., 174; some of the indications for opening the membrana tympani, 176; nasal obstruction with reference to aural disease, Leland, G. A., 199; auditory aphasia, Pershing, H. T., 321; three cases of extra-dural abscesses, operations and recoveries, Green, J. O., 533; acute inflammation of the antrum of Highmore, Cobb, F. C., 594, 603.
- Eczema.** Some obstinate forms of eczema, Abbott, C. S., 353.
- Editorials.** Medical men and their health, 19; dolichocephaly and tuberculosis, 20; Haffkine's plague prophylactic fluid, 42; medical reticence, 67; recent foreign literature on appendicitis, 91; the new tuberculin, 115; a new research laboratory for India, 116; the bacillus feridolus, 116; concerning hysteria, 139; the radical cure of inguinal hernia by injections of chloride of zinc, 163, hernia at the Richmond Asylum, Dublin, 164; poisons in etiology, 184; ether and chloroform, 215; the International Congress: the British Medical Association, 245; the sanitary service of railways and navigation, 272; splenectomy, 288; the new tuberculin, 293; the diminishing death-rate in New York, 300; expert testimony, 323; the influence upon nervous affections of operations upon the female pelvic organs, 325; nature and treatment of Menière's disease, 352; two points of view, 355; congenital dislocations of the shoulder, 359; has the cellular nucleus independent existence? 379; the surgery of the stomach, 400; subcutaneous injections of the salicylate of mercury, 501; Lowell Institute lectures by Professors Darwin and Foster, 426; the heredity of acquired characteristics, 427; is the sympathetic system the seat of the emotions? 450; protection in France against foreign medical practitioners, 451; narcotism and alcoholism, 452; yellow fever, sero-immunization and sero-therapy, 474; a department of public health, 501; meddlingness midwifery, 502; a new method for the radical cure of inguinal hernia, 526; the Michigan monthly bulletin of vital statistics, 527; health legislation in Germany, 554; department of mental diseases at the Boston Dispensary, 579; sewer gas and sewer ventilation, 580; Nicholas Ivanovitch Pirogoff, 604; a forty years' summary of the vital statistics of Massachusetts, 606; the proposed yellow fever commission, 633; treatment of fracture of the patella, 633; on the frequency of plural births, 635; the relative safety of chloroform and ether, 660, the twenty-eighth annual report of the Massachusetts State Board of Health, 661; annual report of the surgeon-general of the United States Navy, 662; notification of measles, 663; annus medicus, 670.
- Edson, C. E.** Notes upon Denver weather, 515.
- Education.** The people of the State of Colorado on relation of Frank Jerome *vs.* the regents of the University of Colorado, 118; the Hahnemann Hospital College and the University of California, 218; physical training, its function and place in education, Hartwell, E. M., 357; the need of medical examining boards, Hamaker, W. P., 581.
- Ehrlich, H.** A case of septic pyelitis following cystitis, as a complication of the puerperium, 441.
- Eichberg, J.** The hot bath in the treatment of pneumonia, 41.
- Eliot, C. W.** Address before the Harvard Medical Alumni Association, 264.
- Elsner's** method of diagnosis in typhoid fever, Richardson, M. W., 16.
- Emotions.** Is the sympathetic system the seat of the emotions? 450.
- Engelmann, G. J.** Remarks on symphysectomy, 34, 37.
- Enteroptosis** as a clinical factor in the diseases of women, Stone, A. K., 332, 348; movable kidney and enteroptosis, Lund, F. B., 335, 346; enteroptosis, Dole, M. P., 345.
- Ether.** The use of ether in obstetric practice, Green, C. M., 198, 205; chloroform and ether, Keele, D. E., 641; the relative safety of chloroform and ether, 660.
- Everett, W. S.** An incident in the history of vaccination, 77.
- Excision** of hip, Townsend, W. R., 161.
- Experts.** Expert testimony, 323; medical expert testimony, a proposed law, 305.
- Eye.** On the occurrence of retinal hemorrhage after middle age and its bearing on the duration of life, Derby, H., 83; anomalies of muscular balance, Wadsworth, O. F., 100; some phases of lachrymal obstruction and their treatment, Harrower, D., 102; contagious conjunctivitis, Standish, M., 129; purulent ophthalmia from the bacteriological standpoint, Bury, W. F., 131; convergent strabismus, Williams, C. H., 151; hemorrhage attending the extraction of cataract, Wadsworth, O. F., 308; the degeneration of eyes, Hiland, T., 371; glaucoma, Carville, H. deW., 372; a case of moon-blindness, Centerville, L. A., 383; the use of tincture of iodine in chronic trachoma and pannus, Baxter, W. E., 417; ocular headaches, Greenwood, A., 644.
- Farlow, J. W.** Subglottic tumor removed by tracheotomy and curetting, 213.
- Femur.** Chondrosarcoma of the femur, Cabot, A. T., 161; four cases of recent fracture of the neck of the femur, Kidlon, J., 162.
- Fever.** Alcohol stimulation in continued fevers, Cabot, R. C., 573.
- Fisk, S. A.** Digestion *vs.* drugs in the treatment of pulmonary tuberculosis, 112; the people of the State of Colorado on relation of Frank Jerome *vs.* the regents of the University of Colorado, 118.
- Fistula in ano.** Palliative and operative treatment of fistula in ano, Blake, J. B., 230.
- Fitz, G. W.** A study of measurements in curvature of the spine, 310.
- Flick, L. F.** The treatment of tuberculosis by iodoform injections, 40.
- Flora.** Study of the American medicinal flora, Rusby, H. H., 22.
- Florida.** Winter Park, Florida, as a winter resort, Chamberlain, C. N., 667.
- Food.** Food nostrums, Harrington, C., 292; the adulteration of food and drugs, 382; the price of bread in Italy and the health of the poor, 439.
- Foot.** The human foot in art, Bradford, E. H., 305.
- Fordyce, J. A.** Symmetrical atrophy of the skin, 425; impetigo herpeticiformis or dermatitis herpeticiformis, 446.
- Foster, M.** Lowell Institute lectures by Professors Darwin and Foster, 426.
- Fox, G. H.** The various forms of pityriasis and their relation to eczema, eczema and psoriasis, 423.
- Fracture** of humerus from muscular action, Meigs, J. V., 13; fractures of the lower jaw and their treatment, Moriarty, P. W., 509.
- France.** Protection in France against foreign medical practitioners, 451.
- Fry, F. R.** Spinal leptomenigitis, 319.
- Fuller, E.** Chronic contraction of the prostatic fibres encircling the vesical neck, 62; tubercular necrosis of the prostate, 63.
- Fussell, M. H.** Perichondritis of the larynx in typhoid fever, 17.
- Gait.** An examination of human gait, Bradford, E. H., 329.
- Gall-stones** formed on the sutures of an operation for cholecystotomy twenty months ago, Homans, J., 13.
- Garceau, E.** Some cases of cystitis, 97, 109, 126, 437.
- Gardiner, C. F.** The dangers of tubercular infection and their partial arrest by climatic influences, 89.
- Gauze Drainage,** Harrington, F. B., 150, 157; notes on surgical gauzes, Hall, H. J., 518.
- Gay, G. W.** A case of ligature of the innominate artery for aneurism, 73, 87.
- Generative System.** Priapism, Taylor, R. W., 62; chronic contraction of the prostatic fibres encircling the vesical neck, Fuller, E., 62; tubercular necrosis of the prostate, Fuller, E., 63; a report of a case of hernia testis, Allen, G. W., 64; the relation of oxaluria and uric-acid excess to genito-urinary inflammations and disorders, Lewis, B., 65; a case of double ovariectomy during pregnancy, Kingman, B. A., 103, 108; a case of ovariectomy during pregnancy, Burrage, W. L., 104, 108; the choice between the abdominal and vaginal incisions in the operative treatment of acute pelvic inflammations, with some remarks upon the technique of the vaginal operation, Reynolds, E., 146, 158; triple glands, 166; recovery from a gunshot wound of the uterus, Neugebauer, 191; the influence upon nervous affections of operations upon the female pelvic organs, 325; treatment of uterine displacements, McMurphy, S. W., 372; a case of emaso menses or absolute amenorrhea in a married woman, twenty-six years old, Burrage, W. L., 394, 398; ventro-fixation with a report of two operations on the same case, Kaan, G. W., 393, 397; lymphangionia of the labia majora, White, J. C., 417; a case of diphtheria of the vulva, Coues, W. P., 410; recent progress in gynecology, Reynolds, E., 548; a case of oophorectomy during labor, Reynolds, E., 647, 654; division of the utero-sacral ligaments and suspensio uteri for immobile retroposition with acute flexion, Burrage, W. L., 652.
- Gerhardt.** The serum test for the diagnosis of typhoid, 16.
- Germany.** Health legislation in Germany, 554.
- Gilchrist.** A discussion upon the X-rays, 423.
- Gilchrist, T. C.** Eleven cases ofrokeratosis (Mibelli) or hyperkeratosis excentrica (Respighi) in one family, 445; pseudo-lupus of the face due to the presence and growth of blastomycetes or budding organisms resembling yeast plants, 446.
- Gillette, A. J.** Traumatic spondylitis, 137.
- Gletschmann, J. W.** Treatment of chronic affections of the tonsils with demonstration of instruments, 185.
- Goat's milk.** An inquiry: use of goat's milk, Parker, W. T., 192.
- Goldthwait, J. E.** Treatment of deformities of the knee resulting from tumor albus, with especial reference to the cases in which the patella has become adherent, 162; drawing of the knee joint, 318; the direct transplantation of muscles in the treatment of paralytic deformities, 489.
- Gonorrhea** in women, Cushing, E. W., 249.
- Goodale, J. L.** A new cutting forceps, 370.
- Goodman, J. E.** Man and medicine, 530.
- Gout,** Hutchinson, W., 41; treatment of gout by natural mineral waters, Ransom, C. C., 113.
- Graham.** The symptoms and diagnosis of cholelithiasis, 351.
- Greeley, G. H.** Acute cerebral meningitis, 373.
- Green, C. M.** The use of ether in obstetric practice, 198, 205.
- Green, J. O.** Some of the general principles which should govern operations for otitic brain disease, 145; three cases of extra dural abscesses, operations and recoveries, 533.
- Greene, R. W.** Remarks on secondary puerperal hemorrhage, with report of two cases, 152.
- Greene, W. W.** Bibliography of articles by Wm. Warren Greene, M. D., 583.
- Greenleaf, R. W.** A case of aceton poisoning, 57.
- Greenwood, A.** Ocular headaches, 644.
- Grindon, J.** A peculiar affection of the hair follicle, 446.
- Gunshot** wound of the head, Swan, W. D., 618.
- Gynecology.** Recent progress in gynecology, Reynolds, E., 518.
- Haffkine's** plague prophylactic fluid, 42.
- Hahnemann Hospital College** and the University of California, 218.
- Hall, H. J.** Notes on surgical gauzes, 518.
- Hamaker, W. P.** The need of medical examining boards, 581.
- Harrington, C.** Food nostrums, 292.
- Harrington, F. B.** Gauze drainage, 150, 157.
- Harrower, D.** Some phases of lachrymal obstruction and their treatment, 102.
- Hartigan, J. W.** An unusual weight for a child at term, 557.
- Hartley, F.** A new method for the removal of diseased processes in the neck posterior to the sterno-mastoid muscle, 409, 421.
- Hartwell, E. M.** Boston Board of Municipal Statistics, 189; physical training, its function and place in education, 357.
- Hartzell, M. B.** Impetigo herpeticiformis, 446.
- Hastings, R. W.** Quinine nose-bleed, 677.
- Health boards** and the Widal test for typhoid fever, Cabot, R. C., 276.
- Heart.** Penetrating wound of the heart, recovery, Parrozzani, 190.
- Heredity** of acquired characteristics, 427.
- Hernia.** The radical cure of inguinal hernia by injections of chloride of zinc, 163; a new method for the radical cure of inguinal hernia, 526.
- Herter, C. A.** Sarcoma of mid-brain in a child, associated with asymmetrical hydrocephalus, 377; pachymeningitis hemorrhagica interna in children, 656.
- Hewes, H. F.** A record of the treatment of four cases of pulmonary tuberculosis with Koch's new tuberculin, 259; the chemical analysis of the gastric contents, 555, 563.
- Hibbard, C. M.** A case of gastric ulcer in a child four months old, 177.
- Higgins, F. A.** A lock for the Reynolds axis-traction forceps, 652.
- Hiland, T.** The degeneration of eyes, 371.

- Hildreth, J. L.** The public care of the insane poor in Massachusetts, 461, 485.
- Hinsdale, G.** Remarks on the treatment of tuberculosis by the anti-tubercle serum, 416.
- Hip.** Late excision of the hip, Lovett, R. W., 7.
- Hoch.** A case of acute insanity associated with definite changes in the internal structure of the nerve cells, 182.
- Homans, J.** Gall stones formed on the sutures of an operation for cholecystostomy twenty months ago, 13; a case of nephrectomy for renal abscess, calculous pyelitis and cholecystostomy in the same patient, recovery, 547.
- Hopkins, F. E.** A case of adeno-carcinoma of the nose, 213; operation for correcting deformity of the nasal septum, 669.
- Horibek.** Address before the American Public Health Association, 322.
- Horses.** Sun-bonnets for horses, 274.
- Hospital and dispensary abuse,** 23.
- Hubbard, L. W.** The prognosis of hip disease under efficient treatment, 162.
- Hughes, J. W.** The drainage, plumbing and ventilation of public and private buildings, 322.
- Humerus.** Fracture of humerus from muscular action, Meigs, J. V., 13.
- Hunter, W.** Cholelithiasis, 350.
- Hurd, E. P.** Sudden death due to alcoholism, 619.
- Hutchinson, W.** Gout, 41; the "skin heart" as a factor in the human circulation, with special reference to the Brand and Schott treatments, 511.
- Hyde, J. N.** A contribution to the study of bleeding stigmata, 423.
- Hydrocephalus.** Chronic hydrocephalus—puncture, Beach, H. H., A., 676.
- Hygiene, Health and Boards of Health.** Report of committee on steamship and steamboat sanitation, Montizambert, F., 521; a study of yellow fever from a medico-geographical point of view, Liceaga, E., 541; the drainage, plumbing and ventilation of public and private buildings, Hughes, J. W., 322; car sanitation, Woodbridge, S. H., 322; address before the American Public Health Association, Horibek, 322; meat inspection, Pearson, L., 523; report of the committee on transportation of diseased tissue by mail, Lachapelle, E. P., 524; consumption as an indoor disease, Abbott, S. W., 524; the urgent need of sanatoria for the consumptive poor of large cities, Knopf, S. A., 524; health legislation in Germany, 554; the bill for a department of public health, Austin, H. W., 559; a department for public health and the American Medical Association, Wingate, U. O. B., 552.
- Hysteria.** Concerning hysteria, 139.
- Ingalis, E. F.** Address before the American Climatological Association, 85.
- Instruments and Apparatus.** A new modification of the hip-splint, Dane, J., 59; gauze drainage, Harrington, E. B., 150, 157; a new cutting forceps, Goodale, J. L., 311; notes on surgical gauzes, Hall, H. J., 51; a new electrical nasal saw, Cobb, F. C., 520; a look for the Reynolds axis-traction forceps, Higgins, F. A., 652.
- Internal medicine as a vocation,** Osler, W., 447.
- Intubation.** A case of intubation at the age of four months and ten days, Taylor, F. W., 239; report of forty cases of intubation, Stevens, C. B., 288.
- Italy.** The price of bread in Italy and the health of the poor, 430.
- Jack, F. L.** Some of the indications for opening the membrana tympani, 16.
- Jackson, H.** A sign of cardiac failure, 467, 473.
- Jacobi, A.** Twelfth International Medical Congress, 94.
- Jacoby, G. W.** Thomsen's disease, 658.
- Jewett, C. P.** The treatment of puerperal septic diseases, 552.
- Johnston, W.** Serum diagnosis of typhoid fever, 455.
- Judd, L. D.** Two remarkable recoveries from malignant diphtheria, 113.
- Jenkins, W.** Recurrent stone in the bladder of a child, 64.
- Kann, G. W.** Ventrifixation, with a report of two operations on the same case, 393, 397.
- Kaserling.** Specimens preserved with their natural color by Kaserling's method, Whitney, W. F., 316; the preservation of specimens with their natural colors by Kaserling's method, Whitney, W. F., 621.
- Keefe, D. E.** Chloroform and ether, 641.
- Ketch, S.** The work and influence of the American Orthopedic Association, 136.
- Kidder, E. H.** Two cases of cholecystostomy, 399.
- Kingman, R. A.** A case of double ovariectomy during pregnancy, 103.
- Kinnear, B. O.** Pneumonia treated by heat over the spine and by the inhalation of pure oxygen, 575.
- Kinnicutt, F. P.** Address before the Harvard Medical Alumni Association, 265.
- Klotz, G. H.** Strong solutions of the ichthyol group in acute and chronic inflammatory conditions of the skin, 421.
- Knapp, P. C.** Anesthesia in spinal diseases, 320.
- Knee.** Tubercular knee-joints, Nichols, E. H., 158; drawing of the knee-joint, Goldthwait, J. E., 318.
- Knight, C. H.** President's address before the American Laryngological Association, 183.
- Knight, F. I.** Choice of a summer residence in New England, 111.
- Knopf, S. A.** Aero-therapeutics and hydro-therapeutics in the treatment and prevention of pulmonary tuberculosis, 59; the urgent need of sanatoria for the consumptive poor of large cities, 524.
- Koch's new tuberculin in lupus,** 142; Koch's new tuberculin, 142.
- Laboratory.** A research laboratory for India, 116.
- Lachapelle, E. P.** Report of the committee on the transportation of diseased tissue by mail, 524.
- Langdon, F. W.** Focal cord lesions, 320.
- Langmaid, S. W.** Sub-mucous hemorrhage of the vocal cords, 184.
- Larynx.** President's address before the American Laryngological Association, Knight, C. H., 183; guaiacol as a local anesthetic in minor operations in the nose and throat, Newcomb, J. E., 184; sub-mucous hemorrhage of the vocal cords, Langmaid, S. W., 184; a further contribution to the study of laryngeal phthisis, Murray, T. M., 213; primary lupus of the larynx, Mayer, E., 213; recent progress in laryngology, Coolidge, A., Jr., 598.
- Leet, J. A.** Phlebotomy, 373.
- Leland, G. A.** The centennial introductory address, Dartmouth Medical School, July 14, 1896, 25; nasal obstruction with reference to aural disease, 199.
- Leprosy.** General conclusions of the International Leprosy Conference, Berlin, 1897, 557.
- Leszinsky, W. M.** Epilepsy following infantile cerebral palsy, improvement after craniotomy and evacuation of subcortical cyst, 377.
- Lewis, B.** The relation of oxaluria and uric-acid excess to genito-urinary inflammations and disorders, 65.
- Liceaga, E.** A study of yellow fever from a medico-geographical point of view, 521.
- Liebmann, G.** My experience with hyperacidity, 465.
- Lincoln, J. R.** Gastric ulcer in the new-born, 178.
- London.** Public health in London, Macdonald, W. G., 610.
- Londonderry, Lord.** Lord Londonderry advocates disease dissemination, 454.
- Lovett, R. W.** Late excision of the hip, 7; spondylolisthesis, 137; fifty resections in hip-joint disease, 138.
- Lowell Institute lectures by Professors Darwin and Foster,** 426.
- Lund, F. E.** Movable kidney and enteroptosis, 335, 346.
- Macdonald, W. G.** In Neisser's hospital, 46; public health in London, 610.
- McMurphy, N. W.** Treatment of uterine displacements, 372.
- Maidstone epidemic of typhoid,** 505.
- Mallory, F. B.** A case of ruptured aorta, 315.
- Malpractice.** Suits for malpractice, Wallace, A. S., 373.
- Man and medicine.** Goodman, J. F., 530.
- Marriage by capture in Arabia,** Holden, E. S., 529.
- Martin, E.** Detection of stone in the kidney, 39.
- Massachusetts General Hospital.** Clinical meeting of the staff, 491; second clinical meeting of the staff, 623.
- Materia Medica and Therapeutics.** Study of the American medicinal flora, Rosby, H. H., 22; the hot bath in the treatment of pneumonia, Eichberg, J., 41; Haikine's plague prophylactic fluid, 42; a case of acetic poisoning, Greenleaf, R. W., 57; a case of atropine poisoning, Vickery, H. F., 59; report on progress in therapeutics, Williams, F. H., 85; a caution against the use of antefibrin on extensively blistered surfaces, Boland, E. S., 95; oil of turpentine as a remedial agent, Walker, J. B., 113; treatment of gout by natural mineral waters, Ransom, C. C., 113; the new tuberculin, 115; guaiacol as a local anesthetic in minor operations on the nose and throat, Newcomb, J. E., 184; chloroform in obstetrics, Davis, E. P., 193, 205; the superiority of chloroform as an anesthetic in midwifery practice, Worcester, A., 196, 205; the use of ether in obstetric practice, Green, C. M., 198, 205; a record of the treatment of four cases of pulmonary tuberculosis with Koch's new tuberculin, Howe, H. F., 259; subcutaneous injections of the salicylate of mercury, 401; remarks on the treatment of tuberculosis by the anti-tubercle serum, Hinsdale, G., 416; the use of tincture of iodine in chronic trachoma and pannus, Baxter, W. B., 417; alcoholic stimulation in continued fevers, Cabot, R. C., 573; report on progress in therapeutics, Williams, F. H., 626.
- Mayer, E.** Primary lupus of the larynx, 213.
- Mays, T. J.** The salicylate treatment of hemoptysis, 90.
- Measles.** The notification of measles, 663.
- Meat inspection,** Pearson, L., 523.
- Medical men and their health,** 19.
- Meigs, J. V.** Fracture of humerus from muscular action, 13; three cases of abdominal stab-wound, laparotomy in each case, with recovery, 597.
- Méniere.** Nature and treatment of Ménière's disease, 352.
- Michigan.** The monthly bulletin of vital statistics, 527.
- Millard, F. R.** Triple glands, 166.
- Mind.** The effect of climate upon neurasthenia and melancholia, Taylor, J. M., 90; a case of acute insanity associated with definite changes in the internal structure of the nerve cells, Hoch, 182; relation of mental diseases to general medicine, Cowles, E., 277, 297; steps toward insanity, Baker, S., 378; two cases of homicidal mania, transitory frenzy, Bancroft, C. P., 385; the insane poor in private dwellings in Massachusetts, Mitchell, A., 457; the public care of the insane in Massachusetts, Hildreth, J. L., 461, 485; department of mental diseases at the Boston Dispensary, 679; characteristics of insanity, Chanung, W. F., 585, 613; the insane poor in private dwellings in Massachusetts, Moulton, A. R., 616.
- Mitchell, A.** The insane poor in private dwellings in Massachusetts, 457.
- Money rouleaux,** 327.
- Montgomery, D. N.** Hereditary and continuous shedding of the finger-nails, 425.
- Montgomery, D. W.** Acquired idiosyncrasy for quinine as shown by purpura and bleeding of the gums, 616.
- Montizambert, F.** Report of committee on steamship and steamboat sanitation, 521.
- Moon-blindness.** A case of moon-blindness, Centervall, I. A., 333.
- Moriarty, P. W.** Fractures of the lower jaw and their treatment, 509.
- Morrow, P. A.** Linear nevus, 423.
- Mortality.** The diminishing death-rate in New York, 300.
- Moscow.** Some recollections of the Twelfth International Congress at Moscow, Watson, F. S., 588.
- Moulton, A. R.** The insane poor in private dwellings in Massachusetts, 616.
- Movable Kidney.** Report of post-mortem examinations in some cases of movable kidney, Watson, F. S., 37; clinical observations on loose and displaced kidneys, Bryson, J. P., 38.
- Murray, T. M.** A further contribution to the study of laryngeal phthisis, 213.
- Muscles.** The direct transplantation of muscles in the treatment of paralytic deformities, Goldthwait, J. E., 489.
- Musser, J. H., and Swan, J. M.** A clinical report on sero-diagnosis, 16.
- Neck.** A new method for the removal of diseased processes in the neck posterior to the sterno-mastoid muscle, Hartley, F., 409, 421.
- Neisser.** In Neisser's hospital, Macdonald, W. G., 46.
- Nelson as a patient,** 166.
- Nervous System.** Intra-tympanic disease as a factor in the cause-

- tion of aural vertigo, Blake, C. J., 5, 14; a case of traumatic cerebral edema, operation, death, White, H. W., and Courtney, J. W., 11; observations on two examples of typhoid meningeal infection, Ohlmacher, A. P., 17; dolichocephaly and tuberculosis, 20; the effect of climate upon neurasthenia and melancholia, Taylor, J. M., 90; diseases of the nervous system affected by climate, Brown, S., 90; climate in relation to the nervous system, Brown, D. R., 114; concerning hysteria, 139; case of temporo-sphenoidal tumor presenting symptoms of abscess, Richardson, W. L., and Walton, G. L., 169; a case of acute insanity associated with definite changes in the internal structure of the nerve cell, Hoch, 182; "carding" the sciatic nerve, Del-genière, 219; clinical report of an epidemic of cerebro-spinal meningitis, Williams, F. H., 311; address before the American Neurological Association, Starr, M. A., 319; primary idiopathic hydrocephalus in adults, Prince, M., 319; spinal leptomenigitis, Fry, F. R., 319; subarachnoid serous exudation productive of pressure symptoms after head injuries, Walton, G. L., 319; focal cord lesions, Langdon, F. W., 320; anesthesia in spinal diseases, Knapp, P. C., 320; syringomyelia, Patrick, H. T., 321; so-called polienccephalitis superior and inferior, Patrick, H. T., 321; auditory aphasia, Pershing, H. T., 321; the influence upon nervous affections of operations upon the female pelvic organs, 325; acute cerebral meningitis, Greeley, G. H., 373; causes and recent treatment of neurasthenia, Quackenbush, J. D., 374; encephalitis with changes in the pia, Wiener, A., 374; Little's disease: shall we retain the name? Sachs, B., 375; the nature and treatment of spasmodic torticollis, Walton, G. L., 375; some interesting cases of brain tumor, Zenner, P., 376; sarcoma of mid-brain in a child, associated with asymmetrical hydrocephalus, Herter, C. A., 377; epilepsy following infantile cerebral palsy, improvement after craniotomy and evacuation of subcortical cyst, Leszynsky, W. M., 377; uncommon nasal parasthetic neurosis, Ayres, S., 378; climate or environment as a factor in the repair of neurasthenia and melancholia, Taylor, J. M., 415; hysterical dermatoneuroses, Van Harlingen, A., 423; is the sympathetic system the seat of the emotions? 450; exophthalmic goitre, Putnam, J. J., 492; acute cerebro-spinal meningitis, Shattuck, F. C., 499; report of a case of asthmatic paroxysms taking the place of epileptic fits, Clark, L. P., 622; two cases of cervical myelitis, Putnam, J. J., 623; ocular headaches, Greenwood, A., 644; a consideration of the parasthetic neuroses, psychroesthesia and kaumesthesia, Dana, C. L., 644; Thomsen's disease, Jacoby, G. W., 656; pachymeningitis hemorrhagica interna in children, Herter, C. A., 656; the pathology and morbid anatomy of Huntington's chorea, with remarks on the development and treatment of the disease, Collins, J., 657; brain desuetude, Erichton-Browne, J., 664; cerebral syphilis, with report of a case of chronic meningo-encephalitis secondary to syphilis, Barney, C. N., 671, 677.
- Newcomb, J. E.** Gualacol as a local anesthetic in minor operations in the nose and throat, 184.
- Newton, R. C.** Some personal observations upon the effects of changes of climate upon men and animals, 112.
- Neugebauer.** Recovery from a gunshot wound of the uterus, 191.
- Nevus.** Linear nevus, Morrow, P. A., 423.
- Nichols, A. H.** Injuries, 181.
- Nichols, E. H.** Tubercular knee-joints, 158.
- Nicoladoni.** Plastic operations on the thumb, 274.
- Nose.** Papillary edematous nasal polypi and their relations to adenomata, Wright, J., 213; a case of adeno-sarcoma of the nose, Hopkins, F. E., 213; operation for correcting deformity of the nasal septum, Hopkins, F. E., 663; the soft catheter in plugging the nose, Smithwick, M. P., 677; quinine nose-bleed, Hastings, R. W., 677.
- Obstetrics.** Chloroform in obstetrics, Davis, E. P., 193, 205; the superiority of chloroform as an anesthetic in midwifery practice, Worcester, A., 196, 205; the use of ether in obstetric practice, Green, C. M., 198, 20; recent progress in obstetrics, Townsend, C. W., 417.
- Ohmacher, A. P.** Observations on two examples of typhoid meningeal infection, 17.
- Opium.** An examination of forty-three published cases of opium or morphine poisoning, Bartlett, E. S., 674.
- Orthopraxy.** The work and influence of the American Orthopedic Association, Ketch, S., 136; erosion of the knee-joint with conservation of the epiphyseal cartilage, Sherman, H. M., 136; traumatic spondylitis, Gillette, A. J., 137; spondylolisthesis, Lovett, R. W., 137; treatment of torticollis, Brackett, E. G., 137; congenital dislocation of the shoulder-joint, Scudder, C. L., 138; a case of asymmetrical development, Shands, A. R., 138; some effects upon the leg of pronation of the foot, Dane, J., 138; fifty resections in hip-joint disease, Lovett, R. W., 138; excision of hip, Townsend, W. R., 161; the prognosis of hip disease under efficient treatment, Hubbard, L. W., 162; treatment of deformities of the knee resulting from tumor albus, with especial reference to the cases in which the patella has become adherent, Goldthwait, J. E., 162; a study of measurements in curvature of the spine, Fitz, G. W., 310.
- Oster, W.** Relapses in typhoid fever, 17; British medicine in Greater Britain, 221; internal medicine as a vocation, 447.

- Spalding, F. M.** Address before the Harvard Medical Alumni Association, 268.
- Spine.** A study of measurements in curvature of the spine, Fitz, G. W., 310.
- Spleen.** Splenectomy, 298.
- Splints.** A new modification of the hip-splint, Dane, J., 59.
- Standish, M.** Contagious conjunctivitis, 129.
- Starr, M. A.** Address before the American Neurological Association, 319.
- Statistics.** Boston Board of Municipal Statistics, Hartwell, E. M., 189; the Michigan monthly bulletin of vital statistics, 577; a forty years' summary of the vital statistics of Massachusetts, 606.
- Sternum.** A case of dislocation of the sternum, reduced, Stone, J. S., 312.
- Stevens, C. B.** Report of forty cases of intubation, 288.
- Stewart, D. D.** An autopsy in a case of innominate aneurism cured by the introduction of gold wire and electrolysis, 275.
- Stewart, J.** Arthritis deformans, 299.
- Stomach.** Chronic ulcer of the stomach, Cutler, E. G., and Elliot, J. W., 54; the surgery of the stomach, 400.
- Stone, A. K.** Enteroptosis as a clinical factor in the diseases of women, 322, 348.
- Stone, J. S.** A case of dislocation of the sternum, reduced, 312.
- Subscription.** Sold only by subscription, Thayer, A. S., 113.
- Suiter, A. W.** The barber shop as a menace to the public health, 223.
- Summer Residence.** The choice of a summer residence in New England, Knight, F. L., 111.
- Sun-bonnets for horses,** 274.
- Surgery.** The new surgery, Cheever, D. W., 1; recent progress in surgery, Burrell, H. L., and Cushing, H. W., 151, 158, 312; points in operative technique, Cabot, A. T., 492; intestinal obstruction from band, Porter, C. B., 494; the injuries of modern naval warfare, Suzuki, S., 610; surgery on the battlefield without anesthesia, Ryan, C. S., 610.
- Suzuki, S.** The injuries of modern naval warfare, 610.
- Swan, W. D.** A gunshot wound of the head, 618.
- Symphysiotomy.** Remarks on symphysiotomy, Engelmann, G. J., 34, 37; case of symphysiotomy, Pomeroy, E. H., 36, 37.
- Syphilis.** Entire destruction of the soft palate and velum by syphilis, Blodgett, A. N., 133, 135; cerebral syphilis, with report of a case of chronic meningo-encephalitis secondary to syphilis, Barney, C. N., 671, 677.
- Taylor, A. E.** Anemia, 42.
- Taylor, F. W.** A case of intubation at the age of four months and ten days, 239.
- Taylor, J. M.** The effect of climate upon neurasthenia and melancholia, 90; climate or environment as a factor in the repair of neurasthenia and melancholia, 415.
- Taylor, R. W.** Priapism, 62.
- Thayer, A. S.** Sold only by subscription, 143.
- Thompson, W. G.** The clinical value of the Widal test for typhoid fever, 478.
- Thornbake, P.** A case of cystin calculus in the male bladder, 40.
- Thumb.** Plastic operations on the thumb, Nicoladoni, 274.
- Tongue.** Subglottic tumor removed by tracheotomy and curetting, Farlow, J. W., 213.
- Tonsil.** Treatment of chronic affections of the tonsils with demonstration of instruments, Gleitsmann, J. W., 185; simulated sarcoma of the tonsil, Delavan, D. B., 212.
- Torticollis.** Treatment of torticollis, Brackett, E. G., 137; the nature and treatment of spasmodic torticollis, Walton, G. L., 375.
- Townsend, C. W.** Phthisis and child-bearing, 391, 398; recent progress in obstetrics, 417; three cases of congenital heart disease, 493.
- Townsend, W. R.** Excision of hip, 161.
- Trained attendants for chronic cases,** 529.
- Trichinosis.** The diagnosis of trichinosis, 676, 678.
- Tuberculin.** The new tuberculin, 115; the tuberculin test in ten cases of acute pleurisy, Sears, G. G., 121; the diagnostic value of tuberculin, White, F. W., 123, 134; Koch's new tuberculin in lupus, 142; Koch's new tuberculin, 142; the new tuberculin, 299.
- Tuberculosis.** Deliccephaly and tuberculosis, 20; results after nephrectomy for renal tuberculosis, Bangs, L. B., 39; how to treat tuberculosis, Rochester, D. L., 40; the treatment of tuberculosis by iodoform injections, Plieck, L. F., 40; curability of pulmonary tuberculosis, Borland, E. B., 40; tubercular necrosis of the prostate, Fuller, E., 63; the dangers of tubercular infection and their partial arrest by climatic influences, Gardiner, C. F., 89; observations upon pulmonary tuberculosis in Colorado, Bonney, S. G., 89, 282; arotherapeutics and hydro-therapeutics in the treatment of pulmonary tuberculosis, Knopf, S. A., 89; digestion *vs.* drugs in the treatment of pulmonary tuberculosis, Fisk, S. A., 112; a record of the treatment of four cases of pulmonary tuberculosis with Koch's new tuberculin, Hewes, H. F., 259; acute tuberculosis in puerperal women, Call, E. L., 342, 350; what inferences may be drawn from cases of pulmonary tuberculosis reported to have originated in Colorado, Bonney, S. G., 362; remarks on the treatment of tuberculosis by the anti-tubercle serum, Hinsdale, G., 416; the tuberculous diathesis, Burr, C. R., 542; record of two cases of beginning pulmonary tuberculosis treated with subcutaneous injections of Koch's tuberculin, T. R., 571, 577.
- Turbinate bodies.** A new method of permanent relief for certain enlargements of the turbinate bodies, Delavan, D. B., 212.
- Turpentine.** Oil of turpentine as a remedial agent, Walker, J. B., 113.
- Tuttle, J. P.** Urethro-rectal fistula, 61.
- Twoibly, E. L.** Antitoxin as a prophylactic, 649.
- Typhoid Fever.** The serum test for the diagnosis of typhoid, Gerhardt, 16; Elsner's method of diagnosis in typhoid fever, Richardson, M. W., 16; observations on two examples of typhoid meningitis infection, Ohlmacher, A. P., 17; relapses in typhoid fever, Osler, W., 17; perichondritis of the larynx in typhoid fever, Fussell, M. H., 17; the rational antiseptic treatment of typhoid fever, West, H. A., 17; the treatment of typhoid fever, Upshur, J. N., 18; the Woodbridge treatment of typhoid fever, Woodbridge, J. E., 94; health boards and the Widal test for typhoid fever, Cabot, R. C., 276; bacterial features of typhoid, with special reference to pathology and diagnosis, Smith, C. D., 295; oysters and typhoid fever, 327; on the bacteriological examination of the stools in typhoid fever and its value in diagnosis, Richardson, M. W., 433; serum diagnosis of typhoid fever, Johnston, W., 455; the clinical value of the Widal test for typhoid fever, Thompson, W. G., 478; Maidstone epidemic of typhoid, 505; the separation for diagnostic purposes, by a new method, of typhoid bacilli from the stools and urine, 505; the Widal test for the diagnosis of typhoid fever, 506; a case of cholecystitis due to the typhoid bacillus, Richardson, M. W., 570.
- Tyson, J.** On the proper use of terms to denote myocardial changes, 270.
- Upshur, J. N.** The treatment of typhoid fever, 18.
- Urinary System.** Cancer of kidney, nephrectomy, Beach, H. H., A., 13; report of post-mortem examinations in some cases of movable kidney, Watson, F. S., 37; clinical observations on loose and displaced kidneys, Bryson, J. P., 38; some observations upon the surgical anatomy of the kidney, Brewer, G. E., 38; results after nephrectomy for renal tuberculosis, Bangs, L. B., 39; detection of stone in the kidney, Martin, E., 39; a case of cystin calculus in the male bladder, Thornbake, P., 40; urethro-rectal fistula, Tuttle, J. P., 61; priapism, Taylor, R. W., 62; chronic contraction of the prostatic fibres encircling the vesical neck, Fuller, E., 62; a new method of removing polypoid growths from the bladder, Chismore, G., 61; recurrent stone in the bladder of a child, Judkins, W., 64; a case of nephrectomy for cystic adenoma in a pregnant woman, Scudder, C. L., 64; a possible aid to the discovery of the tubercle bacillus in the urine, Bryson, J. P., 64; the relation of oxaluria and uric acid excess to genito-urinary inflammations and disorders, Lewis, B., 65; some cases of cystitis in women, Garceau, E., 97, 109, 120, 437; renal diseases as affected by climate, Banforth, I. N., 111; some cases of urethral polypus, Reynolds, E., 413, 445; a case of septic pyelitis following cystitis, as a complication of the puerperium, Ehrlich, H., 441; a case of nephrectomy for renal abscess, calculeous pyelitis and cholecystotomy in the same patient, recovery, Romans, J., 547; a case of chyluria, Vickery, 625.

- Vaccination.** An incident in the history of vaccination, Everett, S. W., 77.
- Van Harlingen, A.** Hysterical dermato-neuroses, 423.
- Vickery, H. F.** A case of atropine poisoning, 59; a report of three cases of cancer of the stomach in which hydrochloric acid was present, 132, 136; two cases of regurgitation and tabes dorsalis, 498; a case of chyluria, 625.
- Vietor, A. C.** The diagnosis of some common injuries in the shoulder region, 412, 439.
- Wadsworth, O. F.** Anomalies of muscular balance, 190; hemorrhage attending the operation for cataract, 398.
- Walker, J. B.** Oil of turpentine as a remedial agent, 113.
- Walking.** A study in human gait, Bradford, E. H., 162.
- Wallace, A. S.** Snits for malpractice, 373.
- Walton, G. L.** Subarachnoid serous exudation productive of pressure symptoms after head injuries, 319; the nature and treatment of spasmodic torticollis, 375.
- Ward, R. DeC.** A visit to the highest meteorological station in the world, 637.
- Warren, J. C.** Anatomical specimens, 602; total excision of the scapula for sarcoma, 624.
- Washington.** Medical laws of the State of Washington, Coe, F. H., 559.
- Water.** Treatment of gout by natural mineral water, Ransom, C. C., 113; report of the committee on the pollution of water-supplies, Smart, C., 523.
- Watson, F. S.** Report of post-mortem examinations in some cases of movable kidney, 37; some recollections of the Twelfth International Congress at Moscow, 583.
- West, H. A.** The rational antiseptic treatment of typhoid fever, 17.
- White, F. W.** The diagnostic value of tuberculin, 123, 134.

Lecture.

THE NEW SURGERY.

THE SHATTUCK LECTURE FOR 1897.¹

BY DAVID W. CHEEVER, M.D., LL.D., BOSTON.

WHAT can it do now that it could not do before?
What can it do better now than it could before?

Anesthesia, as well as asepsis, must answer these questions. The one gave us painless operations; the other painless-healing. One annulled consciousness, the other prevented inflammation; one rendered possible delicacy of manipulation, the other averted suppuration and absorption. Formerly suppuration was frequent, and primary healing rare; now primary healing is the rule, and suppuration the exception. Healing is measured by days, instead of by weeks; surgical fever is nearly always absent. The hectic of suppuration is happily wanting; the chill of sepsis unusual; secondary hemorrhage unknown, unless the result of trauma. Ligatures are buried and encysted or absorbed; sutures are cut and drawn out dry as when put in; pain is little; constitutional disturbance often slight. Scars are less deforming; adhesions less contractile; keloid less frequent; recurrence, locally, more favorably affected. Three dressings take the place of twenty; there are no ligatures to pull away and none to fear to touch, because they may prematurely loosen the stream of some great vessel.

We will try to describe these great changes without exaggeration, and proceed to speak of them in detail.

Let us look back seventy years, to 1827, when the work of Benjamin Travers, F.R.S., senior surgeon of Saint Thomas's Hospital, on "Constitutional Irritation," appeared. Chapter II, "On Examples of Direct Constitutional Irritation induced by Inflammation following Punctured Wounds and Abrasions of the Fingers in Dissection"; and Chapter IV, "On Examples of Direct Constitutional Irritation induced by the Admission of a Poison into the System by a Wound, or Abraded Surface." In Chapter IV are given 16 cases, of which 12 died.

Venesection, cupping, leeches, calomel, antimony, senna, opium, ammonia, stimulants, few and spare incisions, poultices, lead lotion, were the remedies used. It is, however, justice to Mr. Travers to say, that bleeding was soon found to be useless, and a supporting treatment was advocated in the later cases. What strikes one, however, was the absence of anything antiseptic, or cleansing; the too slight use of free incisions, and the malignancy of the symptoms, which ranged from lymphangitis to diffused suppuration of the cellular tissue; to erysipelas of the phlegmonous variety; to gangrene, to sepsis and general pyemia. In varying degree these conditions showed themselves in all the cases, and death followed, in from one to eleven days, in 75 per cent. of those wounded. This sad mortality occurred in one surgeon's practice; mostly from October to January of one autumn term of the medical schools. There were affected: a professor of anatomy, an army surgeon, a naval surgeon, a civil surgeon, four physicians, eight medical students, not to mention an undertaker and a servant. Of the 16 professional men and students, 12 died.

Thirteen cases followed wounds received in autopsies

on persons very recently dead; and three from dissecting-room subjects. In one case, Mr. Newby's, it is instructive to note the contagious, or infectious character of the disease. Mr. Newby opened the body of a child dead of enteritis (*Query*, peritonitis?), and had a pustule appear on a wounded thumb. He had deep-seated pain in the left breast, and a pink tinge there: a tumor from the sternum to the scapula, and from the clavicle to the hypochondrium; fetid stools; a brown tongue; a swollen arm; effusion of brown serum. He died on the eleventh day.

Now mark the consequences. Mr. Jackson, his assistant, had an erysipelatous throat and abscess of the tonsil; his pupil, a low fever; the housemaid, tonsillitis; the nurse, fever and a stiff neck (cellulitis), followed by phlegmonous erysipelas, which was fatal; the woman who laid out Mr. Newby's body had phlegmonous erysipelas, but recovered. Five cases resulting from this one of Mr. Newby's; apparently none who were in contact escaped, except the attending surgeon.

What would be the moral effect to-day, if such an epidemic of preventable poison occurred in our community and carried off twelve persons engaged in the pursuit of pathology and anatomy? Contrast it, if you can, and mark the difference in hygiene, in sanitation, in treatment, in the chances of professional life.

All this occurred in this century, in the great medical centre of London, under the best surgeons, Sir Astley Cooper being one of the consultants.

Mr. Clifton, of Islington, aged thirty-seven, scratched his thumb with a needle while sewing up the body of a female who had died of peritonitis. He was under the care of Dr. Gordon, of Finsbury Square. At three o'clock the next morning he was awakened with excruciating pain in the thumb and forearm; after ten hours the surgeon describes the arm as tense and swollen; very severe constitutional symptoms and pain; nausea, headache, anxiety, oppression in the chest; pulse full, hard, and 120. A large dose of calomel, and bled to 30 ounces; a poultice, a febrifuge and aperient. This was followed by a sleepless night and terrible pain; hand and arm much swollen; red line of absorbents; pain in axilla; appeared much sunken and complained of head greatly. Leeches and cold to temples. Next day, dreadful pain and lack of sleep; hand and arm more swelled; pulse full and hard, and 100. Bled 12 ounces; leeches applied; pulse 130; overwhelming oppression in chest and head; bled 16 ounces; leeches and purgatives. Next night, in agony, no sleep; pulse 120, hard and wiry. An incision made in hand and thumb—a little pus; immediate relief; poultice; fell asleep. During this sleep he bled very largely in the poultice, and fainted. Later, pain returned; pulse rose to 120, full and hard. In three days more, 140 leeches were applied. Then followed collapse, sighing, pulse 140, soft and compressible. Opium was now used freely; he improved; the application of leeches was only necessary twice more, and purging. He recovered.

The streptococci and staphylococci must have found exit with the 58 ounces of blood taken from the veins, and the 140 leeches, and have been also eliminated by the purging. What is noticeable, from our point of view, is that all these heroic measures were taken to allay inflammation—whereas inflammation was a symptom only of the putrescent germs running riot in the blood.

¹ Delivered before the Massachusetts Medical Society, June 8, 1897.

From this time on, mostly in war, but also in peace, hospital gangrene prevailed occasionally, down to twenty years ago. In civil general hospitals, wards had to be closed on this account; while pyemia and hospitalism were often fatal to the wounded as well as to the puerperal woman.

The fate of a compound fracture is a good barometer, or measure, of the healthfulness of a hospital, and of the sanitary success of treatments. From 1864 to 1869, about thirty years ago, we learn from the first quinquennial report of the Boston City Hospital, there were treated 120 compound fractures. Of these over one-half (66 per cent.) came to amputation. Of the compound fractures of the upper extremity 41 per cent. died; of the lower extremity 60 per cent. were fatal. Of those amputated, the thigh had a mortality of 56 per cent.; the arm 38 per cent.; the leg 32 per cent. One-sixth of the deaths were from pyemia; and there were four cases of tetanus. Such were the results during the first five years of a new and well-equipped hospital. Nor was this sad record much at variance with the other great hospitals.

During the sixth and last period of five years (1889 to 1894), being the experience from this hospital when twenty-five years to thirty years old, although the beds had increased from 250 to 800, the number of amputations had fallen from 132, the first five years, to 82. Of the 132, the first five years, the total mortality was 49 per cent.; but of the 82 amputations, the last five years, the total mortality was 16.75 per cent.; one-third as large as thirty years ago. Amputations of hip, 50 per cent. instead of 100 per cent.; amputations of thigh, 12.5 per cent., instead of 56 per cent.; amputations of leg, 13.5 per cent., instead of 32 per cent.; amputations of arm, 16.5 per cent., instead of 38 per cent. In other words, few compound fractures came to amputation; of those few the mortality was less by two-thirds than formerly. What other adequate cause can be found for so vast a change unless it be asepsis. The patients were of the same class; the accidents were the same; the hospital wards the same; many of the surgeons the same.

In curious confirmation of these proofs of asepsis come a series of recent events which is a crucial test.

Late in November, 1896, a sudden move of the entire surgical plant to the new operating-rooms was made, and made unexpectedly, on account of the urgency of a contractor engaged to tear down the old amphitheatre by December first. New hands had to be employed in a part of the sterilizing process; a new sterilizer was also being tried; everything was thus altered from its habitual use for months previously. Failure of asepsis promptly followed. Stitches suppurated; stitch abscesses burrowed; 13 cases of absorption, covering the three surgical services, occurred; some serious cases of sepsis; so that all but emergency cases were refused operation.

An "emergency committee" of three surgeons proceeded to hunt for germs, three to six hours each day; and in this they were vigorously assisted by Dr. Councilman's department. Cultures from silk, from catgut, from gauze, from sheets, from instruments, were made; more than one hundred in all. The search was immediately rewarded by finding streptococci and spores in the sutures, ligatures, towels and sheets; the gauze, which was baked separately, was free and sterile. The fault was largely in the too low temperature of the new sterilizer. An entirely new bacillus was found in

the catgut, which produced abscess in the guinea-pig when injected in its culture. A spore-bearing bacillus was found on the sheets used at operations. This yielded only to two bakings, twenty-four hours apart. If baked at short intervals it was not killed, because this spore was found to hatch and grow in twenty-hour intervals.

In one week of hard work the trouble was nearly subdued; and soon the wounds resumed their usual course of primary aseptic healing. It was a demonstration, and perhaps worth what it cost.

This brings us naturally to consider the first great advance in the new surgery. And that is, that under its dressings, we can safely wait, after an accidental injury, an indefinite time, before operating.

All older surgeons must recall the precept, then imperative, that while we might wait after an injury for reaction to succeed shock, we must not wait too long. There was a golden moment, between twelve, eighteen, at most twenty-four hours after an accident, when amputation must be done. Unless this golden moment was availed of, then surgical fever succeeded reaction; suppuration invariably ensued; and while inflammatory processes were going on, and until pus flowed freely, no operation should be done. This intermediate stage was a fatal stage, prone to tetanus, to sepsis, to metastatic inflammation. The necessity of operating on the second, third or fourth day after a wound, in our late civil war, explained the large mortality from tetanus and gangrene which resulted.

Operate early, or operate late; primary amputation within twelve hours of the injury; or, after a week to ten days, secondary amputation on a case become pathological by suppuration. Experience proved this to be the true method.

Under the new surgery all this may be done away with. The lacerated limb is shaved, scrubbed, irrigated, packed and dressed aseptically. One may wait indefinitely; suppuration does not ensue; fever and absorption will not occur, provided the antisepsis is complete; and provided the limb is not fatally injured and past repair.

Wait and see how the injury will turn out. Wait and see whether the parts can heal of themselves and save the limb. Wait in the surety that when you take down the dressing the cuts will look as fresh and clean as when they were inflicted. Under this aseptic *regime* then we wait for shock to be all gone; we wait to see if a compound fracture cannot heal itself. The majority do heal, and amputations become rarer and rarer.

Next, healing is painless. This is a new thought. After the subsidence of the pain of the incisions, lasting a few hours, there should be no more pain in aseptic healing. The clinical thermometer should barely rise, if it rise at all.

Late experiments at our hospital have proved that surgical fever, so-called, steadily diminishes as asepsis improves. Imperfect asepsis, a few germs in the dressings, or an infected suture, surgical fever; fair asepsis, no more germs than the vitality of the tissues can handle and destroy, slight fever; perfect asepsis, no stitch abscess, no effusion or draining, no surgical fever and painless healing. It is a demonstration; and it has been demonstrated.

Contrast this with the course of events formerly, after the removal of a breast. Surgical fever; fifteen ligatures to come away; drainage by the ligatures;

suppuration; a daily dressing; a sinus; probably some stitches suppurating and failing to hold; a granulating surface, drawn together with adhesive plaster; fever; pain; ligatures to be pulled daily. Such patients recovered, but they suffered for several weeks.

To take a perfect case of new surgery. A lady, whose breast I removed, told me, after she recovered, that she had had no pain. Ether first annulled it, and she declared she had had no real pain in the dressings or in healing. This is an extreme case.

The new surgery does away with secondary hemorrhage. Why? because the ligature does not come away, but stays on the vessel. Ulceration through the coats of the artery is not to be expected, as formerly, hence the vessel does not give way and bleeding follow. We tie the carotid and the wound heals over the buried ligature of boiled silk, or asepticized animal tendon, by first intention. The vessel is closed when the string is tied; it stays closed, and there is the end of it.

Could John Hunter rise and admire this new use of the ligature to treat an aneurism, near the sac, with no fear of secondary hemorrhage; could Ambroise Paré only see his ligature safely enclosed and encapsuled in the stump of an amputated thigh. Primary union; a smooth scar; no pain; no hemorrhage; no suppuration.

These triumphs of asepsis in ordinary wounds seem small, however, in comparison with what it has accomplished in visceral surgery. Opening serous cavities with impunity, and with a mortality for simple exploratory celiotomy of from three to five per cent., seem to the older surgeon almost incredible. Formerly the abdomen was a hidden and sacred region; now it is thrown wide open. If it is safe to open the abdomen, then it is idle to wait for the growth of cysts of the ovary, but better to remove them before adhesions form. If it is safe, why not remove the appendix when it is not acutely inflamed? Such are the claims of asepsis: we cannot assent to them all, however.

To take another region: in the first five years of the City Hospital fractures of the vault of the skull were equally fatal (60 per cent.) whether trephined or not. Now trephining is used with comparative safety to explore for clots, to remove ganglia, to search for tumors, even to relieve pressure. The pleural cavities and the pericardium have also been opened, as never before.

The value of explorations has been much increased by anesthesia. This is the result of, first, absence of feeling on the part of the patient; and, second, of the relaxation of the muscles. No question of diagnosis and possible operation on the contents of the abdomen or of the pelvis should be considered settled without an examination under ether. The gain in knowledge, and the enhanced accuracy in diagnosis, are very great. Bi-mannual examination of tumors of the abdomen, and of the pelvic organs in the female, is made easy and reliable by ether. The rectum, also, is thus rendered accessible.

Many are tempted by the immunity of aseptic surgery to incise the abdominal walls for diagnosis. While explorations are thus made needlessly, still the final risk may be only of a scar or a hernia. Grave reasons should be the only excuse for such incisions; and while we are spared the former risk of sepsis, still if the explorer disturbs or handles malignant disease, the subsequent danger is considerable. Chronic peritonitis of the tubercular variety yields the best results from ex-

ploratory laparotomy and drainage; but acute, diffused peritonitis is as fatal as before the days of asepsis.

In orthopedics, in opening joints, and in the radical cure of hernia, asepsis has substituted the open incision for the more clumsy subcutaneous methods of Diefenbach. While atmospheric air was once recognized as hostile to primary healing, it is now proved to be harmless, provided clean hands, instruments and sponges touch the wound.

Antiseptic spray is abandoned as a needless precaution. The knee-joint is safely opened to wire a broken patella, and the *évidement*, or the excision of joints, formerly the pride of the conservative surgeon, is now boldly advanced from a justifiable risk to a certain success.

The golden stitch of Paré, revived by Wood in the subcutaneous suturing of the abdominal rings, has given place to the free, open incision and dissection of Bassini, in the radical cure of hernia.

Club-foot and tarsal deformities are cut open and repaired, and knock-knee is chiselled into shape, without fear or scruple.

The sensitive serous lining of the spinal canal is dissected, pared and matched, to enclose a spina bifida. Fracture and dislocation of the spine is made compound and repaired with questionable audacity, uncertain result, but yet with aseptic triumph. Hydrocephalus is tapped and microcephalus expanded, by the same surgical boldness, without fatality, but without final cure.

The sensitive ganglion of Gasser is torn from its hiding-place, with a mortality of only 20 per cent., but with little lasting benefit.

But when we look at the successful treatment of large, open surfaces caused by burns, we must yield our unqualified admiration. Who has not seen, twenty-five years ago, the burn so large it could not heal. The wretched victim perished from chronic irritation. Now, skin-grafting and transplantation freely and aseptically cover the largest granulating area with a new epidermic shield; and healing takes place without disastrous cicatrices and contractions.

The treatment of gangrene—traumatic, diabetic or senile—has been much improved. High amputation in traumatic gangrene is now justified, without waiting for a line of demarcation, since sepsis, in this moist variety, frequently outruns the walling off of nature. And the aseptic and buried ligature has enabled us to amputate the atheromatous vessels of age and senile mortification with a fair degree of success.

The curetting of cold abscesses and packing them with antiseptic gauze have hastened their repair, and proved curative; but only provided the source of suppuration could be removed, as in a joint. Meanwhile the flaxseed poultice has been replaced by hot fomentations of corrosive gauze, thus checking pus formation in acute abscess. Pus is still brought into hospitals; but little pus is engendered in them. Hospitalism is a myth, where once a terror.

It may be confidently asserted that grave surgical injuries and operations are safer in a hospital than in their own homes, however luxurious. Sanitation, scrupulous cleanliness, discipline, drill, ceaseless vigilance, skilled nursing (night as well as day), attendance of trained care-takers, and above all antiseptics and asepsis, have brought about this marvellous success.

Pyemia was the opprobrium of surgery and the

fatal disease of hospitals. Sepsis decimated the lying-in retreat. Both are so far subdued, that suppuration and absorption are regarded almost as a fault; and puerperal blood-poisoning as a neglect of due precaution, in many instances. This is a strong assertion, and may be questioned, but statistics answer for it, to a large degree.

But when we approach the large class of chronic diseases, we are forced to pause in our enthusiasm. Tubercle, cancer and sarcoma are, as yet, unconquered. Setting aside the inoculations of Koch, and regarding only the treatment of tubercle by the knife and gouge, it is not yet proven that evident tubercle, as in lymphatic glands, should always be removed. Neither pulmonary nor miliary tuberculosis always follow tuberculous glands in the neck, if left untreated. Many children grow up and have long lives, whose so-called scrofulous glands have scarred their necks by suppuration in their early years.

"It is a familiar clinical fact, that the operative treatment of joint tuberculosis has not infrequently been followed by tuberculosis of the other organs, or by general miliary tuberculosis."²

Cancer is a degeneration; it is seculity, often premature. Could a germ be found, an antitoxin might succeed. Cancer spreads; becomes disseminated; attacks other tissues. New cancer grows in the lymphatic glands, and in other parts. "The reproduction of similar structure is an argument against the microbic origin of cancer."³

Cancer is an atypical proliferation of cells from a matrix of embryonic epithelial cells. The new epithelial cells, like the ameba and leucocyte, possess the power of locomotion, or migration. Here is the fatal fact, and the reason for dissemination. We see cancer cells sprinkled like dust over the mesentery and peritoneum in abdominal cancer. Generalization of cancer takes place in consequence of the entrance into the circulation of cancer cells, or fragments, which when arrested, like emboli, constitute new centres of cancerous growth. It is this cell migration, and the intrinsic capacity of the cells to reproduce themselves in new localities, that constitute malignancy. For example, in 18 cases of cancer of the pylorus, Senn found only one case limited to the pylorus; in 17 the lymphatic glands were also affected.

Here operation could be only palliative, and not curative. Nodules in the skin and in the lymphatics are the rule of dissemination in cancer of the breast. Later, one may be sometimes attracted by an arching out, or prominence of the sternum, on the affected side. Here we may suspect cancer in the medulla of the sternum. The bronchial and mediastinal glands are next involved; then the pleura and the liver. Obviously the surgeon's knife can only be curative in those early or exceptional cases, where the misplaced cells are local, and have not migrated. All operations, however extensive, at a later period must be wholly uncertain as cures; and recurrence is the rule, sooner or later.

Sarcoma is an atypical proliferation of connective-tissue cells. The small, round cells migrate freely through the muscular interspaces, by the sheaths of the vessels, through the vessels, rarely by the lymphatics. Sarcoma gives rise to regional or general infection at an earlier stage than cancer. It is vascular and

rapidly growing. Hence a very early operation is the only thorough one. Local recurrence is more common than general.

Sarcoma is the tumor of young and vigorous life; cancer, the degeneration of seculity; tubercle hatches in the nest of childhood and adolescence. We have here, then, three diseases incurable by the knife. Anesthesia and asepsis may charm, but they will not cure. We have to look for a different class of remedies: the erysipelas toxin, the streptococcus toxin; chemical solvents? What, we know not yet. But through this path only can finally be secured immunity from occurrence, recurrence and death from these malignant affections.

While admitting freely the great benefits sometimes conferred by judicious surgeons, yet the New Surgery is in danger of injury and degradation from the tendency to over-operate. This is a very grave charge, but it is true.

We can open the abdomen safely; why not look in, or wait for halting diagnosis? Having looked in, if we find anything operable we remove it. A healthy appendix; a fibroma, or a cyst like a marble; a drooping uterus to hang up; a sinuing ovary to rebuke, and take out of the way of farther mischief.

We leave Nature no chance. But be sure she will get even with us in the end. The expected relief from removing pelvic organs does not always follow. The sensibilities of nerves cut away are referred back to their terminal branches, as we see in amputations. Neuralgia, menstrual nisis, flows of serum, supplement the normal function. The patient is unable to work, and is, moreover, unhappy. Meanwhile Nature teaches us, by her laws of compensation, that an operation is not always necessary. A dilated bladder overflows; an obstructed bowel leaks by serious diarrhea, and the unbearable load is washed away. So time and physiological rest will often alleviate the ills of pelvic indurations and inflammations.

Will operations increase in frequency? We think not; but there will be a conservative reaction that will tend to diminish them. Also, the advance in bacteriology will diminish them still more. Traumatic surgery we shall always have; but pathological surgery will be lessened by new antitoxins. Meanwhile we must not overlook the changes which the New Surgery is causing in the surgeon himself. First, he is specialized. Necessary preparation and special study are so much increased, that he must pay attention to surgery only to be successful. Second, his responsibility is increased with his knowledge. The electric light pierces opaque tissues, and clarifies a diagnosis, before doubtful; or shows misplacement in a fracture, so that the dullest juror can see it. The anatomy of the viscera opens up a new field of study for the surgeon. He operates no better than his predecessor, but he must know more.

Surgery is less simple than formerly. When to operate in appendicitis, and when to forbear, open up a new set of anxieties for the surgeon; redness, heat, pain, swelling, fluctuation, guided the knife formerly; now leucocytosis and the thermometer must also be consulted.

The surgeon of to-day needs general professional training, first, so as to promptly recognize and treat any medical complications, such as pneumonia, pleurisy, the exanthemata. Next, clinical experience to appreciate gross appearances. Then, regional anat-

¹ Senn: Limits of the Art of Surgery.
² Senn: On Tumors.

omy; training in bacteriology; a competent knowledge of the mechanical and chemical details of asepsis. Restrained by broader knowledge and with a judgment tempered by experience, the new surgeon will offer to the world only such operations as are nearly sure of success; thus benefiting the public health, which was the object of its founder in endowing the Shattuck Lectures.

INTRA-TYMPANIC DISEASE AS A FACTOR IN THE CAUSATION OF AURAL VERTIGO.¹

BY CLARENCE J. BLAKE, M.D.

NOTWITHSTANDING the work which has been done in the study of aural vertigo, the field presented both for observation and conjecture is a very large one, since it deals both with a peripheral and a central organ of equilibration, and has numerous reflex connections which bring it into sympathy with other portions of the body remote both in the physical and physiological sense. It is the purpose of this paper, therefore, merely to draw attention to such gross interferences with the peripheral organ of equilibration as may serve to explain in a minor degree the simplest form of causation of a complex of symptoms which is found in varying extent throughout the whole class of vertiginous cases in which the ear plays a part.

A consideration of the structure of that portion of the labyrinth devoted to equilibration (a study in the simplest sense, schematical it almost might be called) shows a bony cavity filled with an incompressible fluid into which project the tactile organs transmitting to the nerve cells the ultimately appreciable motion. All movements communicated through this fluid are of the to-and-fro order, whether they be the minute transmission of the pulsatory movement of sound waves, or the grosser forms of impulse due to the less delicate movements communicated by means of the sound-transmitting mechanism of the middle ear from the outer air, or through the body by transmission through its bony framework, or solely through the medium of the circulation.

It stands to reason that if the deviation from a line of equilibrium of a ciliate body projecting into the lumen of a semicircular canal, produced by the inertia of a body of fluid from three to five millimetres in length, and less than half a millimetre in diameter, can cause distinct symptoms incident to the sense of motion, that a permanent deviation of a ciliary body from its normal position, as a result of pressure upon the body of the fluid into which it projects, would bring about a sense of motion, the permanency of which would be dependent upon the continuance of the pressure or the sensory adaptation to the abnormal condition.

It is somewhat after this fashion that we may, with our present knowledge of the structure and functions of the equilibrating organ of the labyrinth, construe the effect which would be produced by any pressure from without exerted upon the body of fluid, within which the tactile end apparatus of the posterior branch of the auditory nerve is located. This pressure

from without may be induced in a more or less constant degree by pressure upon the membrane of either the oval or round window, and in lesser duration, though probably not in lesser degree, by increased blood pressure and consequent dilatation of the vessels within the labyrinth.

As has been shown by the early experiments of Burnett and others, any degree of movement of the base plate of the stapes inward upon the membrane of the oval window means a corresponding degree of movement of the membrane of the round window outward, and, *vice versa*. It stands to reason that where the excursion of the stapes inward exceeds the limit demanded for the transmission of the longest sound wave of the lowest musical tone appreciable as such by the human ear, the displacement of the fluid may be such as to exert a definite effect of deviation from the normal line of the ciliate bodies projecting into the ampulla-like endings of the semicircular canals, in point of fact, however, there would seem to be in some cases, a region of immunity between the displacement incident to the longest sound wave and the grosser movement which may induce symptoms of disturbance of equilibration, and it is not, therefore, until the displacement of the fluid in the labyrinth has become a distinctly mechanical one that this peripheral displacement is translated in the sensorium into the sense of a displacement of the body in space.

Two facts are shown from the clinical observation of cases of distinctly aural vertigo, first, that the sense of degree of disturbance of equilibration is, all other things being equal, in definite relationship to the degree of fluid displacement induced by mechanical causes, and, second, that the auditory nerve offers no exception to the general rule of acquired toleration of a disturbing influence of a degree within the possible limits of compensation. Given, therefore, a degree of fluid displacement in the semicircular canals consequent upon inward pressure of the base plate of the stapes which shall cause symptoms of vertigo, it is understood that even with a continuation of the displacement, the vertiginous symptoms may gradually decrease and finally disappear, because of the gradually acquired toleration of the abnormal condition, and be reawakened only by such further increase of displacement as might be due to a still further incursion of the stapes, or to the increased intra-labyrinthine pressure incident to an increased circulation in the blood-vessels within the labyrinth, or an increased vessel dilatation with increased blood pressure consequent upon a suspense of vaso-motor inhibition of reflex origin.

The following cases will serve to illustrate the grosser forms of mechanical disturbance, which sometimes result in the production of what may be called distinctly *aural* vertigo.

A woman, fifty years of age, who had, as a result of a suppurative inflammation of the left middle ear in childhood, a destruction of the larger portion of the drum-head, and the formation of cicatricial bands firmly attaching the lower end of the long process of the malleus to the inner tympanic wall, had, in consequence of a severe acute naso-pharyngeal catarrh, a recurrence of the suppurative process in the middle ear, with the formation of granulomata in the posterior superior portion of the tympanum and neighborhood of the stapes. But little attention was given by

¹ Read before the Boston Society for Medical Improvement, January 25, 1897.

the patient to the symptoms incident to this condition until a sense of fulness and pressure on that side of the head supervened, gradually increasing in degree, and being further complicated by light but continuous sensations of vertigo, together with a distinct subjective circulatory tinnitus increasing, together with an increase of the sensations of fulness and pressure, when finally the patient was obliged to take to her bed, as any attempt to maintain an erect position was accompanied by a degree of vertigo which made attention to household duties impossible. An examination of the ear made at this time showed a firm granulomatous mass projecting downward, below the posterior superior border of the tympanic ring and consequently covering the region of the stapes, and the incus was either absent or enclosed in the granulomatous mass; when sitting up in bed for purposes of examination the patient had to be supported, and any movement of the tumor, especially direct pressure inward and upward, induced an excessive degree of the already almost unbearable vertigo. The removal of the granulomatous mass was evidently indicated, and this was effected piecemeal by means of curved forceps, with intervals of rest for manipulation, necessitated by the increased vertigo and accompanying nausea which the movement of the tumor caused. During the process of morcellation, it was found that the incus was absent, and with the final removal of the larger portion of the mass which pressed directly upon the head of the stapes, there came a sensation of relief from the more exaggerated symptoms, and both the vertigo and the sense of fulness and pressure, and, in a measure, the tinnitus, disappeared during the subsequent three days of rest and recuperation in bed.

A man, thirty-two years of age, who had suffered from suppurative middle-ear disease in childhood, with entire cessation of discharge from the ears for several years, had contracted a severe cold, followed by sensations of pain and fulness in the depth of the ear and a slight, thin muco-purulent discharge. To this symptom he paid but little attention, and continued his work as a clerk, until he noticed a sensation of fulness and pressure in the ear, slowly increasing, and culminating in an attack of vertigo, with nausea and vomiting, and a degree of instability which made it necessary for him to leave his work. When first seen he was in bed, with a slight degree of constant vertigo, which was greatly increased by any movement of the body, and especially by an attempt to sit erect; in the latter position there was a constant tendency to fall toward the left. The right ear was intact, but showed evidences of a past suppurative process; an examination of the left ear showed destruction of the membrana tympani and of the membrane of Shrapnell, and through the opening above the short process of the malleus, enlarged by previous destruction of the soft parts, there were visible a few points of granulation tissue and shreds of desquamated epidermis. With a cotton-tipped probe the granulations were removed, and by means of the forceps a sufficient amount of the epidermis was extracted to give a distinct sensation of relief from the symptoms of pressure and vertigo, and to permit the introduction of a middle-ear syringe. Repeated washings finally effected the entire removal of a cholesteatomatous mass, which, accumulating in the upper and posterior portion of the epitympanum, had by pressure downward upon the head of the incus effected such change in the position of the stapes as

would serve to account for the symptoms of vertigo relieved by removal of the impacted mass.

These two cases illustrate sufficiently the grosser form of pressure which may induce vertiginous symptoms, and may be taken as representing the simple uncomplicated aural vertigo. In the first case, the pressure exerted was apparently upon the head of the stapes, crowding it inward; in the second, the pressure which pushed the incus downward tended both to force the stapes farther into the fenestral niche, and also to carry it toward the inferior niche wall, except in so far as movement in this direction was interfered with by the pull of the stapedius muscle. In the first case, moreover, the incus being absent, and the continuity of the ossicular chain, and its counteracting effect upon the action of the stapedius muscle being broken, the unhindered contraction of the stapedius would tend to pull the head of that bone toward the posterior niche wall, to tilt the posterior end of the base plate inward, and the anterior end outward, and so increase the tension of the basal ligament as to counteract in a measure the tendency toward pressure of the stapes inward from the weight of the superincumbent granulation mass.

Clinical experience in the mobilization of the stapes, as well as anatomical investigation, has shown that the stapes in position in the fenestral niche under normal conditions is, when separated from its articulation with the incus, and its attachment to the stapedius muscle by division of its tendon, in the position of a loose plunger rather than that of an armature firmly attached to a tense basal membrane, the conditions of tension requisite to the operation of the stapes in connection with the ossicular chain and membrana tympani being furnished by its relation to the other portions of the sound-transmitting apparatus, including the stapedius muscle, and by resistance of the body of fluid within the labyrinth. Of the two muscles of the sound-transmitting apparatus which counteract each other, the tensor tympani is by far the larger, and the duration of its action is apparently correspondingly longer than that of the stapedius, a certain degree of contraction of the tensor tympani muscle taking place, and being expended in bringing the articulating facets of the head of the malleus and incus into closer apposition before the counteracting contraction of the stapedius muscle begins. The articulating facets on the head of the malleus locking more firmly against the facets on the head of the incus tend to carry the body, and, therefore the long process of that bone downward, as well as tilt it inward, and this pressure transmitted through the incudo-stapedial articulation carries the head of the stapes downward toward the inferior niche wall, and counteracts the pull of the stapedius muscle; confirmatory clinical evidence of this effect is shown in the relatively greater frequency of adhesions between the head and the crura of the stapes with the inferior niche wall in old cases of suppurative disease of the middle ear, and the pull of the tensor tympani muscle toward the limit of its effective work in drawing the long process of the malleus inward, as best seen in cases of suppurative middle-ear disease where the membrana tympani has been destroyed, and the malleus may be pulled inward unhindered.

Turning now to such cases of non-suppurative disease of the middle ear as may serve to illustrate the point which is here taken, and leaving out of consideration those cases of bony fixation of the stapes

which, as has been shown by the sections of Politzer, serve not only to render the stapes immobile by bony growth springing from the edges of the oval window, but even to displace that bone, and encroach upon the space of the labyrinth itself, we find in advanced cases of simple chronic catarrhal inflammation of the middle ear, a general thickening of the tympanic mucous membrane, a contraction of the tensor tympani muscle, or secondary contraction of its tendon, the membrana tympani being very much indrawn, and a high grade of deafness aërially, with either correspondingly increased, or markedly decreased hearing by bone conduction, the same immobility of the sound-transmitting apparatus, which prevents the passage of sound waves inward, either interfering with the passage of sound waves outward, and so making them more plainly heard within, or by a greater degree of pressure causing a suspense of function of the sound-transmitting structures of the cochlea.

While the intra-labyrinthine pressure thus induced may interfere with the function of the sound-receiving portion of the labyrinth, it may not be sufficient in degree to affect the equilibrating portion, and while not sufficient in degree to affect the equilibrating portion in itself, it is a factor in the causation of aural vertigo, in the sense that, coupled with sudden and occasional increase of intra-labyrinthine pressure due to circulatory disturbances, the two together may bring about a degree of irritation of the semicircular canal end apparatus sufficient to induce the familiar vertiginous symptoms.

Under normal conditions, an increased intra-labyrinthine pressure resulting from vessel dilatation causes not only a movement of the intra-labyrinthine fluid through the safety channels provided for it, but also a certain degree of movement of the membrane of the oval and round window, especially the latter, outward. Given a fixation of these parts, one possible element of compensation for increased intra-labyrinthine pressure is lost, and a lesser degree of intra-labyrinthine vessel dilatation will be required to bring about disturbances of sensation in the equilibrating apparatus. This is the case sometimes in the steadily progressive cases of intra-tympanic thickening in which the disease progresses through many years to a very high grade of deafness and in which, after middle life, may be sometimes noted, in addition to the gradual impairment of hearing for sounds aërially conveyed, the occurrence of at first a slight, and then a more annoying and even fatiguing degree of circulatory tinnitus, and a still higher grade of deafness; finally, the symptom of a slight, persistent dizziness, or of occasional attacks of more marked vertigo, apparently traceable to incidental conditions of increased cerebral and intra-labyrinthine circulation consequent upon long nervous strain and overtire, culminating at last in a sudden suspense of vaso-motor inhibition.

A woman, forty-two years of age, married, with three healthy children, keeping a large house, having many social as well as family demands upon her time—fatigued, moreover, by the effort which she had to make, under these conditions, to compensate for an impairment of hearing of several years' standing, and which was slowly increasing—began to notice slight symptoms of dizziness when first waking in the morning, and occasionally in the daytime after prolonged exertion. The dizziness increased rather than diminished, and she had finally a distinct attack of vertigo

without localization of direction in movement, and with a tendency to fall forward. During the two or three days' rest following this attack of vertigo, the general dizziness became less, but increased as she again resumed her usual vocations; and after a second marked attack of vertigo, I had an opportunity of making an examination. The hearing was decreased in both ears, especially the left, to an extent which made participation in ordinary conversation impossible, though the voice of a single speaker in the ordinary conversation tone could be heard, and words plainly understood at a distance of three feet, and in the left ear at a distance of less than two feet. The hearing for the tuning-fork by bone conduction was increased in both ears; objective examination showed opaque and indrawn drum-heads; and the history gave the symptoms of a slowly progressive chronic non-suppurative disease in both middle ears. In order to test the degree of influence of the patient's general condition upon the causation of the vertigo, as well as upon the further decrease of hearing which had more recently evidenced itself, instead of attempting local treatment, the patient was directed to take advantage of an opportunity to leave home and make a prolonged visit to a sister living upon a large farm and was given instructions as to diet, exercise in the open air, special injunctions as to rest and sleep, and was put upon small doses of quinine sulphate (one-eighth grain every two hours).

At the end of six months of restful life, the patient returned to her home and her duties. She was free from dizziness; had had no attack of vertigo for three months; had less tinnitus aurium and there was a moderate degree of improvement in hearing. She continued well for nearly two years, when the dizziness, preceded by slowly increasing circulatory tinnitus, returned, and an attack of vertigo, more severe than any previously experienced, occurred. Another period of rest was sufficient to again relieve these symptoms. Three years later when seen again, the patient had in the interval been well, had successfully passed the menopause, and had no further increase of deafness than might be reasonably expected in the time which had elapsed in a chronic progressive case of that character.

LATE EXCISION OF THE HIP.¹

BY ROBERT W. LOVETT, M.D., BOSTON.

AN article dealing with excision of the hip need no longer begin by a comparison of the merits of excision and conservatism as routine methods of treatment. Whatever the sentiment of the surgical world may have been ten or fifteen years ago, it is now generally admitted that on the whole, conservatism is preferable to operative measures. This view is supported by the weight of surgical opinion in America, in England, in Belgium and France and even in Germany. Certain radical surgeons who regard tuberculosis as a malignant affection still advise early and radical measures whenever a tuberculous focus appears in a hip-joint and especially if suppuration occurs² (Bradley, Steiner, Cazin, Daniel, Molliere, Wright, Barker).

But if there is agreement as to the advisability of conservatism on general grounds, there are often

¹ Read before the American Orthopedic Association, at Washington, D. C., May 7, 1897.

² Gangolphe: *Maladies infect. et parasit. des Os*, 1894, p. 332.

many differences of opinion expressed as to the time when conservative should yield to operative measures. The opinion of the surgical world in this regard is of interest.

In France, Ollier⁸ seems to dictate surgical opinion in this matter. He writes: "Abscesses are opened; but if they recur, if they are accompanied by phenomena of absorption, if the hip remains painful and does not tend to ankylosis, if the acetabulum is diseased, resection is formally indicated."

One may assume that Vincent, of Lyons,⁴ is a fair exponent of this policy, to which he agrees in his writing; and it is interesting to note that in 233 cases of hip disease treated at the Charité Hospital, where this policy was followed, 52 were resected, being at the rate of 22.3 per cent. of all cases. At the Children's Hospital, Boston, in 1,100 cases, 50 were resected, being at the rate of 4.54 per cent. This comparison seems to indicate that French conservatism is five times as operative as is American conservatism.

Menard⁶ probably represents French opinion in general, in stating that, "Resection ought not to be reserved for desperate cases; if one wishes to obtain good results the operation must be done in time."

Agén, Lambotte,⁶ another recent French writer, says of excision, "we are of the opinion that as soon as pus exists in the capsule the best way of rapidly curing the patient is to resect without delay."

Nor can French results from operation be adjudged as altogether satisfactory, when Ollier teaches that the most desirable result after resection is complete ankylosis, and Montoz⁷ would nail the femur to the acetabulum after operation to obtain this. Yet one must remember French conservatism expects very little; for Vincent writes, "It is ankylosis in good position (without resorting to resection) that we pursue as the ideal of a cure in coxalgia."

In Germany the tide sets strongly in favor of conservatism. As Jalaquier⁸ has put it somewhat graphically: "The Volkmanns, the Leisrinks and the Koenigs, who were resection mad (*atteints de résécomaine*), are now reacting, and are defending conservative operations."

Sasse⁹ believes that conservative measures can be followed in 75 to 80 per cent. of all cases (leaving 20 to 25 per cent. of cases for excision), an estimate practically the same as Vincent's.

Bruns,¹⁰ reviewing forty years' work at the Tübingen clinic, found 600 cases which he reduced to 390 cases of authenticated hip disease; and of these, 69 were resected, making about 18 per cent., a proportion not far from those of the other Continental surgeons just mentioned.

Schede, Helferliche, Gussenbauer, Von Bergmann and others at the German Surgical Congress in 1894, advocated conservative as contrasted with operative measures.¹¹

English opinion is of two sorts: one, represented by the enthusiastic advocates of early excision, one of whom¹² would remove the head of the bone "as soon as it is suspected that caseation is advancing in it," while another asserts that "treatment short of excision,

when once suppuration occurs, is useful only as a palliative or means of temporizing."¹⁸ The other point of view, the more conservative, is represented by Mr. Watson Cheyne.¹⁴ He would advocate excision, as follows: "(1) Where the disease is progressing rapidly, where tenderness does not subside under treatment, where the fulness in the groin increases, where starting at night continues and where the shortening rapidly extends"; (2) where primary acetabular disease is present; (3) where true dislocation has occurred.

In the United States conservative measures (for the most part in the form of ambulatory treatment by a splint affording protection and traction) are persisted in, on the whole, longer than in Europe. When conservative measures fail to give relief the propriety of excision is considered; but opinion differs widely as to the indications for its performance. Some ultra-conservatives believe that excision is practically never called for, and would treat the most advanced cases to the end by traction and fixation. In general, however, American surgical opinion favors what is known as late excision.

The practical question is this,¹⁵ Is excision of the hip a satisfactory operation done late; when traction and fixation have failed? There is no question of the utility and generally satisfactory results of a fairly early excision of the hip, as shown by a large mass of statistics. The results may perhaps be inferior to a similar series of cases treated by the best conservative means, but many useful legs result, and the mortality percentage is low after the operation. The present paper is wholly directed toward the question of excision of the hip done after conservative measures faithfully tried have failed—one might almost say, excision of the hip done as a last resort.

At the Children's Hospital, Boston, the attitude toward excision of the hip has remained practically unchanged for eighteen years. From 1878 to 1895 inclusive, some 1,100 cases of hip disease have come to the hospital for treatment, and 50 cases have been excised. Conservative treatment at this hospital, as a rule, has consisted of protection, partial fixation, and traction to the joint. In general this is applied by means of the long traction-splint in connection with crutches and a high sole on the well foot. Activity is restricted to certain hours, but ambulatory treatment is preferred to recumbency where possible. Confinement to bed is ordered for patients with sensitive joints, deformity or abscess. Abscesses are opened as they occur. The general condition of the patient is cared for by general hygienic measures.

The indications for abandoning conservative measures for operation, as accepted at this hospital, have been in general as follows:

- (a) Persistent failure of the general health.
- (b) A progressive destructive process in the joint, which continues in spite of favorable therapeutic conditions. This is made evident by much induration and multiple indolent sinuses through which the products of the disintegration drain rapidly away.
- (c) The persistence of severe pain and excessive tenderness late in the disease, which are not affected by efficient traction and fixation.
- (d) The formation of extensive sequestra in the joint.

¹⁵ *Journal American Medical Association*, July 7, 1894.

The object of the following analysis is not primarily to investigate and tabulate the mortality (this has been done again and again in other series of cases), but incidentally to note the mortality, and really to study the condition of the cases in which this operation was done, and especially to note the character of the end-results in those cases where it can be ascertained.

The first case on the list was operated on in 1877, the last case in October, 1895. Of the whole 50 cases, only eight have been operated on since 1892, so that in the majority of all cases an interval of three or four years at least has elapsed between operation and the time of writing.

The incision in use has been one of the posterior ones. Traction on a bed-frame was generally used for some weeks after operation, and a protection splint for the joint has been required for months, and oftener for years, after operation.

The group consists of 50 cases.

Mortality of the 50 cases. Nineteen are known to be dead, and three others were doing so poorly six months after operation that they undoubtedly died—a known mortality-rate of nearly 50 per cent. It is of interest in this connection that Schmidt (quoted by Laurent) found in 116 resected hips that after two and one-half years from operation only four per cent. died of tuberculosis; and after this period he considered them practically safe.

Of the 19 fatal cases, four died within a week after operation, probably of shock and exhaustion; seven died in the year after operation of generalized tuberculosis for the most part; four others died from two to six years after operation; and in the other cases it is simply known that the patients died. One or two had amyloid degeneration of the viscera; one or two died from causes apparently not connected with the disease; but in most cases the cause of death was either generalization of the tuberculosis, or exhaustion, obviously due to the long drain on the system.

It does not seem likely that a closer analysis of the fatal cases would add anything to the figures on the subject or be of especial value.

The practical value of such an investigation should lie chiefly in the definition of the class of cases operated on and the character of results obtained.

The age of the patients at the time of operation was as follows:

Two years	2
Three years	1
Four years	6
Five years	4
Six years	9
Seven years	6
Eight years	6
Nine years	2
Ten years	6
Eleven years	3
Twelve years	3
Not stated	2

The duration of the disease at the time of operation, as estimated from the statements given by the parents, would be of little value and would make the time too short in most cases. The duration of several cases in the group is, however, striking:

Four had lasted	3 years at least.
One had lasted	4 years at least.
Two had lasted	5 years at least.
One had lasted	6 years at least.
One had lasted	8 years at least.
One had lasted	9 years at least.

Although it is not possible to formulate it satisfac-

torily, it may be said that the cases ultimately coming to operation, for the most part did not receive proper attention at home, and were irregular in attendance at the clinic. They were, as a rule, neglected cases. Some had never been under treatment anywhere when admitted to the wards for operation.

The symptoms most prominent in the late history of cases coming to operation were excessive pain and sensitiveness, much porky induration about the hip and profuse discharge from the sinuses.

The condition of the joint at the time of operation was of much interest, as showing how severe and extensive was the disease for which these operations were done; and a consideration of them is of especial value in showing that in the more severe and extensively diseased cases a favorable outcome is not impossible.

In the 50 operations, the great trochanter was removed 47 times, along with the head and neck. This was necessitated by the extent of the disease. Three times only was the section made between the trochanter and head. Eight times it was noted that the shaft of the femur was more or less extensively diseased. Where the shaft of the femur was noted as extensively diseased, the patient generally died, but one case did well where the bone was removed (in a girl of ten) two inches below the lesser trochanter.

The condition of the acetabulum was of much interest, and especially so because so far as one may judge from these cases perforation of the cavity was not necessarily the accompaniment of the gravest cases. The condition of the acetabulum was not noted in 12 cases; three times it was noted as normal or nearly so; two times it was noted as diseased or as containing sequestra; fifteen times perforation had occurred. Supposing that the later condition was one of much gravity, the writer analyzed these cases as to the outcome. Of the 15, three are dead and one likely to die; five are in good condition, as reported below; and one was doing well one year after operation. In five the present condition is not known. This is not far from the rates of mortality in the whole group of cases.

Finally, of the 50 cases, 19 are dead; of the remaining 31, three were doing poorly when last heard from (six months after operation) and probably died. Others were heard from as doing well, as follows:

One	4 months after operation.
Five	6-8 months after operation.
One	9 months after operation.
One	10 months after operation.
Two	12 months after operation.
One	18 months after operation.
One	24 months after operation.

Nothing can be said of the present condition of these patients. They could not be traced.

The interest lies chiefly in the remainder, the cases where the present condition is known.

The detailed notes are as follows:¹⁰

CASE 42. The leg was amputated for osteomyelitis of the femur persisting after excision. The boy is well. The stump is healed and he is a bicycle rider. Fourteen years since operation.

Discharge profuse. Many sinuses. Patient steadily losing.

CASE 9. A bad result as to shortening, position, etc., probably due to removal from hospital against advice. Ankylosis in abduction, eversion and flexion. Shortening of about six inches. Slight lateral curvature beginning. Eleven years since operation.

¹⁰ The condition before operation is printed in the small type.

Many sinuses. Leg and thigh swollen and edematous. Temperature 104°. Parents delayed consent to operation one month.

CASE 19. Seven years and a half since operation. Sinuses healed. Motion of 80° in flexion and a few degrees in abduction. Can stand on operated leg. Uses crutches still, but advised to discontinue them.

Hip and knee on same side diseased. Thickening of trochanter. No abscess. Pain persistent and uncontrollable. Operation chiefly for painful condition.

CASE 23. Six years since operation. Wears no splint, and walks on affected leg without trouble.

CASE 31.

Motion in flexion 25°, abduction 30°, rotation 35°. Shortening of four inches.

Drunken mother and neglect at home. Abscesses and sinuses. Much thickening about joint. Flexion and abduction. Deformity of leg. Temperature 102°. General condition wretched. The operation was performed at two separate times, the patient being too weak to stand it all at once.

CASE 25. Six years since operation. Health good. No crutches for three years. Sinuses healed one year after operation. One inch shortening.

Neglect at home. Leg flexed and adducted. Much spasm and pain. No motion in joint.

CASE 26. Five and one-half years since operation. Walks well without crutches. No splint for a year. Sinuses healed for two years or more. Shortening one inch. General health good, and endurance is as good as the average.

Disease had existed nearly two years. No motion in hips. Much swelling and very painful. General condition failing.

CASE 31. Five years since operation. Shortening five and one-half inches. Motion in flexion 60° in rotation and abduction a few degrees. Can bear

whole weight on operated leg. General condition excellent. Sinuses healed.

An old, untreated case. Condition very bad. Diagnosis of rheumatism had been made some months before outside of hospital and no apparatus used. Thigh flexed to 100°, sinuses and very painful.

CASE 33. Five years since operation. Shortening one and three-quarters inches. General health excellent. Walks without cane or crutch. Wearing a protection splint. Motion in flexion 40°, a few degrees of motion in rotation and abduction.

Treated for once a year. Leg splint. Abscesses opened, etc. Condition gradually getting worse. Sinuses. Much swelling about hip. Tenderness and pain.

CASE 36. Four and one-half years since operation. Condition excellent. Can walk without splint or

CASE 50.

crutches. Sinuses healed. Motion in flexion 65°, in abduction and rotation half of normal. Shortening one inch.

Under treatment three and one-half years. Abscesses had been opened and sinuses persisted. There was much thickening and little or no motion in joint.

CASE 39. Four years since operation. Can walk without splint. Shortening of two inches. Motion in flexion 45°, abduction normal. Condition good.

Much hectic. Hip very sensitive. Thigh and hip extensively swollen and indurated. Hip held in flexed position.

CASE 42. One year since operation. General condition good. Shortening about three inches. Motion of 40° in flexion, and a few degrees of abduction. One sinus still open. Using a traction splint.

Flexion deformity and no motion in hip. Trochanter one and one-half inches above Nelaton's line. Old sinuses open.

CASE 43. One year since operation. General condition excellent. Shortening one inch. Sinuses open. Can bear whole weight on operated leg. Motion in flexion to 65°, rotation normal.

Swelling so great that a large firm tumor occupied the upper

thigh, dense and tender. Five sinuses reaching one-third of the way down the thigh. No motion in joint.

CASE 44. One year since operation. Sinuses healed. Shortening two and one-half inches. Condition excellent. Can stand and walk on operated leg. Motion in flexion to 45°, rotation and abduction nearly normal.

Hip flexed to right angle. Very sensitive. Much thickening about trochanter. Sinuses discharging profusely.

CASE 45. Fifteen months since operation. General condition excellent. It was so bad at the time of operation that she was too weak to sit up. Sinuses are opening. Shortening one and three-fourths inches. Motion to 45° in flexion, rotation one-half of normal.

Hip very sensitive and flexed and abducted. No motion. Temperature 102°. Not gaining in general condition.

CASE 46. One year after operation. Very sick at home. Destructive process has continued in spite of excision. Exhaustion from profuse destructive suppuration is bringing about a fatal issue.

No motion. Hip very painful. Much edema and swelling. Sinuses. Poor general condition. Consent to operation delayed by parents.

CASE 50. Acetabulum perforated. Bone removed for an inch below trochanter. Condition five years after operation: Motion apparently perfect except in abduction. No apparatus used. Sinuses healed. No pain. Patient walks without apparatus. Length of right leg, 25 in.; length of left leg, 27½ in.; circumference of right thigh, 15 in.; left thigh, 13 in.; circumference of right calf, 9¼ in.; left calf, 11¼ in. Leg can be fully extended and flexed.

Hip very sensitive, grating on motion. Several discharging sinuses. Much swelling. Failure in general condition.

These cases require no comment. They are all the cases which could be traced; and in many of them time enough since operation has elapsed to warrant the consideration of them as ultimate results. As an advocate of the use of fixation and traction in all cases to the latest possible moment, the writer hopes that a consideration of these cases may lead to the conclusion that late excision often produces excellent results.

Clinical Department.

A CASE OF TRAUMATIC CEREBRAL EDEMA: OPERATION, DEATH.

BY H. WARREN WHITE, M.D.,
Instructor in Clinical Medicine, Tufts Medical School,

AND J. W. COURTNEY, M.D.,
*Assistant to the Physicians for Diseases of the Nervous System,
Boston City Hospital.*

THE following case fits in so beautifully with that reported by Drs. Walton and Brooks in a recent issue of the *JOURNAL*,¹ and has proven of such extraordinary interest to the writers that they beg leave to submit its report as a further contribution to the study of cerebral edema following trauma, although they fully realize that the evidence of autopsy is lacking.

CLINICAL HISTORY, BY DR. WHITE.

The patient was a man aged thirty, married, and by occupation, a travelling salesman. His family and

¹ Observations on Brain Surgery Suggested by a Case of Multiple Cerebral Hemorrhage. Drs. Walton and Brooks. April 1, 1897.

previous history were unimportant. On March 19, 1897, while on business in Lowell, he was thrown from a carriage about 8 p. m., striking on the right parieto-temporal region. After the accident he arose to his feet, refused a glass of water which was offered to him, and then sank into complete unconsciousness. He was almost immediately removed to the Lowell Hospital, and consciousness returned the next morning at 5 o'clock. During this time there was no vomiting and only a slight amount of nausea. For the next two days he remained at the hospital and, with the exception of headache, was quite comfortable. On the morning of the fourth day his wife arrived at the hospital and found him up and dressed, waiting impatiently for her, as he expected to take an early train for Boston. He was allowed to go, under protest, by the hospital physicians in charge, and returned to Boston on the noon train, taking a parlor-car section. He did not complain of jarring, although he walked and sat down slowly, as if these movements hurt him. He walked unaided from the train to a carriage and from the carriage into his house, sat down for a few minutes and then, with slight assistance, made his way upstairs to his chamber where he had to be undressed and put to bed.

I saw him later in the afternoon. At that time he talked easily and, excepting a headache and pulse of 42, seemed perfectly natural. Examination showed a small contusion over the right parietal region and some swelling of right side of face. The pupils were equal in size and reacted normally to light. The eyes were somewhat red, but no paralysis was anywhere present. The urine was passed normally, but the bowels had not moved since the accident. His family reported that he had appeared dull and stupid, had kept his eyes shut and refused to talk.

Fifth day. Pulse 44, temperature 99° F. Treatment consisted simply of laxative for bowels, bromide for headache, and evaporating lotions to head. Milk diet.

Sixth day. Some difficulty in persuading patient to stay in bed. Found out that he went to bath-room yesterday. Bromide increased.

Seventh day. Consultation with Dr. Geo. W. Gay, who emphasized the importance of keeping the patient in bed however well he felt, and advised continuance of symptomatic treatment.

Eighth day. Pulse 52, temperature normal. Patient restless, conscious, and determined to have his clothes and go to business. Headache still present, mostly on right.

From the eighth to the tenth day no change. On the tenth, Dr. Courtney saw him with me, and careful examination failed to detect any symptoms which were of localizing value. The tenderness over the right parietal eminence still persisted, but the mental condition was fairly good, and outside of a slight increase of the deep reflexes on the left, the examination from a neurological point of view was negative. In Dr. Courtney's opinion there had been either a slight hemorrhage or a decided contusion to the right cortex outside the motor areas, with enough resultant local edema and pressure to cause not only the psychical disturbance, but also the somewhat exaggerated condition of the deep reflexes and the slowness of the pulse. In view, however, of the gradual amelioration of all symptoms, it seemed fair to hope for a final absorption of the effused material, and a further continuance of

symptomatic treatment was advised, with the injunction that the patient should be carefully watched for the slightest symptom of motor disturbance, in which case it was deemed advisable to trephine at once.

Up to the twelfth day the pulse had gradually risen in frequency to 70, and the temperature continued normal. The mental condition also improved somewhat and the patient took nourishment freely.

At my morning visit on the fourteenth day the patient was found in good condition, with normal temperature and good pulse. He had taken his nourishment freely, and seemed to be on the high road to recovery. At 10.30 A. M. he was suddenly seized with what the family described as a trembling over his whole body lasting fifteen minutes. Both Dr. Courtney and myself were summoned and reached the bedside at about 12.30. The patient was lying on his left side, unconscious and breathing stertorously. The face was cyanosed and the facial veins congested; the carotids pulsated forcibly; the eyes were closed. Temperature in right axilla 103°, in left 102.5°. The pupils were equal in size, dilated, but reacted to light. No ocular or facial palsy was apparent. The mouth was open and the tongue retracted. The right arm and both legs were in constant motion, but the left leg was not moved as vigorously as the right. The left hand and arm were extremely paretic, but were moved when forcibly pricked with a pin. Both deep and superficial reflexes were abolished on left, lively on right.

Interpreting the condition as a generalized pressure of the entire right cortex from the extension of a focal lesion for the position of which the predominance of the paresis in the left arm seemed to point to an area, not in, but adjacent to the arm centre, it was decided, in view of the deepening coma, to operate at once.

The situation was fully explained to the family and their consent to operation gained. Dr. Gay was telephoned, but could not be reached. Dr. John C. Munro was then summoned, and on his arrival the condition was explained to him. In his opinion there was no question as to the necessity for immediate operation, so the head was shaved and prepared. At about 2.30 the operation was started, Dr. Edward H. Nichols assisting.² The patient was very lightly etherized, a semicircular flap made in the scalp and an inch trephine opening made over the arm centre on the right side. On removing the trephine button the dura bulged somewhat into the opening and did not pulsate. On opening the dura the brain pushed out moderately, but without pulsation. The pial veins were much distended. There was no evidence of fracture of either table in the region of operation. A probe swept round between the dura and pia showed an excess of edema in all directions, but a director passed first into the substance of the brain directly under the arm centre and then into the ventricle failed to show anything further. With rongeur forceps the trephine opening was enlarged, and the dura opened more freely. For a few moments pulsation returned, only to disappear before completion of the operation. Although the brain bulged moderately, it was not markedly tense as one finds it in cases where the ventricles are distended, and no evidence of hemorrhage was found between skull and cortex.

² For the details of the operation and for other assistance in the case, the writers desire to express their indebtedness to Dr. Munro.

The patient's pulse grew considerably weaker toward the close of operation, but it reacted well to strychnine. Respiration was quiet and apparently normal. Temperature (axilla) 103.5°. Later in the afternoon the pulse dropped from 110 to 96, and the patient rested easy. One-fiftieth of a grain of strychnia sulph. was given subcutaneously every hour, and at 8.30 P. M. the temperature was found to have dropped to 101.5°.

Saturday, fifteenth day. Quite weak all day. Pulse 110-116, respiration 26-30, temperature 100-102°. Patient much easier than before operation; coma and paralytic symptoms not so marked. Left arm moved somewhat. Nutrient enemata partly retained: urine passed involuntarily. Subcutaneous injection of strychnia continued all day at hour intervals. In the evening the respiration began to assume the Cheyne-Stokes character, and the pulse intermitted.

Sunday, sixteenth day. Gradual failure all day. Examination in A. M. (Dr. Courtney) showed: Eyes closed; pupils equally dilated, but responded readily to light; no ocular or facial palsy. The right arm and leg normal; the left arm and leg paretic, but not so much so as before operation. Superficial reflexes abolished, left; lively, right. Deep reflexes lively both sides, but more so on right. Coma deeper. Respiration shallow and sighing.

Toward noon the pulse had risen considerably and could not be influenced by strychnia; the respirations numbered 41-42. Death at 4.30 P. M.

No autopsy was permitted; but after death the dressings were removed and found to be deeply saturated with serum. The wound looked healthy.

CONCLUDING REMARKS, BY DR. COURTNEY.

The conditions found on operation in this case were so strikingly like those found in that of Drs. Walton and Brooks that I cannot help feeling that the pathological process was identical in kind, if not in position; and I do not consider that I am assuming too much when I entirely neglect the consideration of the question of fracture or extensive hemorrhage.

Clinically there were several points of such marked difference in the two cases as to make them worthy of comparison. In theirs, there was early dilatation and slow reaction to light of the pupils, increased pulse-rate and paralytic symptoms. In ours, the pupils were normal in size and in their reaction to light almost to the end; the pulse was slowed to 42 at first, and did not reach 70 until the twelfth day; furthermore, no paralytic symptoms were present until the fourteenth day.

As points of resemblance, it may be noted that both patients began to go to pieces on the fourteenth day from onset, and that the total duration of the illness in both was about sixteen days.

To Dr. Walton the decided contraction of the face, and other indications of pain which he elicited by pressure over the injured area in his case during the unconsciousness which was present the night after the injury, made him think of the trance-like condition produced in young women by severe concussion. In our case marked evidence of pain on pressure over the injured area could be elicited during the period of deepest coma.

It would appear from a study of these two cases that the symptoms presented are of extremely little value as indicating either the position or the extent of

the effusion, and that we ought to place a very definite limit to the time we should wait for resorption even where the symptoms continue to be psychical and not paralytic. Personally, I should be strongly inclined in the future to do a lumbar puncture at the end of the first week, even though the symptoms were purely psychical, and if immediate amelioration did not follow, to supplement this procedure by trephination, for this case demonstrates very clearly the uselessness of the latter operation after the brain has so far suffered from pressure that unconsciousness has supervened.

Dr. Walton asks: "Should we trephine in cases of local edema?" I do not believe that the diagnosis of local edema can be made even where one can absolutely exclude hemorrhage and gets an early monoplegia or hemiplegia. In this connection it is worthy of note that in our case the predominance of the paresis in the left hand and arm proved to be of absolutely no diagnostic significance as to the location of the point of greatest intensity of the pathological process.

There is one further point which this case seems to me to demonstrate very clearly, namely, the great toleration of the brain for pressure which is gradually increased. In conclusion I would remark, that, even before reading Dr. Walton's paper, I was strongly impressed by the conditions of this case as a possible clue to what may go on in the brain, in lesser severity, in the cases of so-called traumatic hysteria.

FRACTURE OF HUMERUS FROM MUSCULAR ACTION.

BY J. V. MEIGS, M.D., LOWELL, MASS.

MRS. S., aged fifty-six, healthy and of muscular build, while engaged in screwing a rubber nipple on a nursing-bottle, felt a snap in her right arm, which was immediately followed by a sharp pain, with complete loss of power. I saw her in less than half an hour after the accident, and on examination found an oblique fracture of the right humerus at junction of upper and middle third.

REGULAR Meeting, Monday, January 25, 1897, the President, DR. A. L. MASON, in the chair.

DR. J. HOMANS presented

GALL-STONES FORMED ON THE SUTURES OF AN OPERATION FOR CHOLECYSTOTOMY TWENTY MONTHS AGO.

I have specimens here which I think are interesting and instructive. They are some gall-stones formed on the sutures of an operation for cholecystotomy twenty months ago. There are two good-sized ones, nearly one and a half inches long. Here are some colored pictures of them.

The woman from whom these were removed came to me from Cavendish, Vt., with a history of nine or ten years' illness. She had been under treatment for many years. She had been in hospitals at times for

months. Her symptoms were backache, incessant vomiting, etc., feeling as if a string was tied round her and she had pain in the backbone, as she expressed it; great distress in the epigastrium; emaciation. She had been in bed eight months before she came here. Dr. Pease washed out the stomach for a fortnight, with some relief; but the woman was so miserable and so suffering that I thought I would do an operation, and that I should probably find salpingitis at least. The uterus was fixed, and there was an enlargement in the left side of the pelvis. I made an opening in the pubic region, and took out a tubo-ovarian cyst on the left side. The bleeding was so free I could not tie all the vessels in the pelvis, so I put on five compressing forceps and left them sticking out of the wound. Not being satisfied that what I removed was a sufficient cause for her symptoms, I put my hand and forearm into the abdomen through the wound, reached up to the liver, and found the gall-bladder full of gall-stones. I sewed up the pubic incision and made another one parallel to the cartilages of the ribs and took out 97 gall-stones. They were about one-fifth of an inch long on the average. It was such a nice clean case that I thought I would sew up the gall-bladder. I put a piece of gauze in the bladder to keep the bile from running out, and made a beautiful seam. I then put in the external sutures. Later, I found I was a piece of gauze short and had to remove my stitches. Feeling it would take a good while to sew up the gall-bladder again, I united its edges with sutures of silk to the peritoneum and put in a rubber tube, and drained. At the end of five weeks she went home well. She weighed about one hundred pounds.

She gained flesh and strength until she weighed 204 pounds, and has been well until about six weeks ago, when she began to have constant vomiting and a return of her former symptoms. I wrote for her to come to St. Margaret's again. About a week ago I made an incision through the old scar and came down on the gall-bladder, which was adherent to the scar; I opened it and found seven gall-stones. An interesting thing is that they have crystallized round these sutures with which at the time of my operation I sewed the gall-bladder to the peritoneum. The sutures became detached, dropped into the gall-bladder, and the biliary salts crystallized round them. All these gall-stones have formed within twenty months, and probably within seventeen or eighteen. I think that is quite a short time. I take it that these pieces of silk acted in the same way as strings suspended in a saturated solution of hot alum do; as it cools, the alum crystallizes around the strings. I think it is rare to have recurrent gall-stones, and very rare to be able to state the exact time it has taken for a gall-stone to form.

CANCER OF KIDNEY: NEPHRECTOMY.

DR. H. H. A. BEACH: At the last meeting I presented a kidney that had been removed for sarcoma. That patient has gone on in uninterrupted convalescence.

Within a week from that time this kidney was removed from the left side of a man sixty years old. The water-color drawing by Miss Byrnes, of the Harvard Medical School, illustrates very beautifully the projection of the disease into the pelvis of the organ, as well as the unusual contour of the bosses on its surface. The patient, while lifting a heavy stone into a boat fifteen years ago, felt something snap in his back

and fell over into the water. He was disabled for a number of months, but was finally able to attend to light work and had no special symptoms from the injury.

• Three years ago he began to pass a small quantity of blood with his urine. This has slowly increased in quantity and frequency until it is now practically continuous, accompanied with vesical pain and tenesmus. There was no pain in the lumbar region, and only a slight resistance to pressure in the direction of the kidney could be detected. His anemia was marked. An attempt was made with ergot and hydrastis to control the hematuria so that a cystoscopic examination of the bladder could be made. The bladder was sounded, but no calculus could be detected. The prostate was enlarged. The bladder was carefully washed out, but no evidence of papilloma could be found in the washings. As the bleeding would not yield to internal medication, and as a cystoscopic examination was impracticable, it became necessary to open the bladder to explore the region. It was done by the suprapubic route. Large clots were found—the bladder perhaps one-third full. They were old, partially adherent and too firm to break down easily. They were sufficient to cause a good deal of tenesmus, whenever there was an attempt at passing urine. The bladder was thoroughly cleared, washed out, and no evidence of any malignant disease or papilloma found, though the bladder-wall was soft and would tear in places like wet paper. Hemorrhage stopped, and he recovered very well from the operation; the tenesmus was relieved through the continuous drainage of the bladder, and he went on very comfortably for a week, when the hemorrhage recurred.

He had been so much more comfortable after the operation that he demurred at the idea of anything more in the way of surgery. In the meantime a mass could be felt deeply in the left lumbar region, with some tenderness, and the hemorrhage was going on. As soon as he decided upon the operation, the anterior incision was made and a second kidney found before removing the diseased organ. The kidney was excised without difficulty, as there were slight adhesions. The disease had infected the glands in the immediate vicinity of the kidney, and had extended to those about the aorta. He sank on the following night from the long-continued hemorrhage, pain, the exhausting effects of the disease, and shock. His blood at the time of the operation had the appearance of a mixture of red ochre and water.

DR. CLARENCE J. BLAKE read a paper on

INTRATYMPANIC DISEASE AS A FACTOR IN THE CAUSATION OF AUDITORY VERTIGO.¹

DR. G. L. WALTON: The neurologist comes in contact with no symptom which causes more difficulty in diagnosis than vertigo. It is my routine custom, in investigating each symptom, to ascertain the length of time it has lasted, whether it was of sudden or gradual onset, whether it has been continuous or intermittent, its seat and its character; then to question regarding accompanying symptoms. The first point regarding the character of vertigo is always to ask whether it is a general tendency to whirl around (or for bodies to seem to be turning around) or whether the tendency is for the person to fall in a definite direction, forwards, backwards or sidewise. If the latter is the character,

I have been accustomed to consider as a rule that the dizziness was aural (or auditory, as the case may be). Again, when the dizziness has come on in paroxysms, the patient falling suddenly forward, as in the case Dr. Blake has just reported, the dizziness should be classed under this head. With regard to the symptoms which accompany the case under investigation, we should look for tinnitus and deafness. If these symptoms are present the chances are still more in favor of the aural or the auditory vertigo. The next step is to investigate the condition of the ear itself, for which purpose I always refer the case to an aurist, but often find in such cases the report quite negative or comparatively negative, namely, that the local condition is not sufficient to explain fully the vertigo, although there may be some slight aural disturbance. In this event we have to consider from how many directions we may have a vaso-motor disturbance which will increase the intra-labyrinthine pressure and produce an auditory vertigo without disease of the ear itself.

Woakes elaborated some time ago the anatomy of the blood-supply of the labyrinth, and showed that the point of departure for sources of irritation was the lower cervical ganglion, near which the vertebral artery passes, and from which it receives a branch. This artery supplies the inner ear through the internal auditory, a branch of the basilar. He shows that this inferior cervical ganglion receives also a branch from the pneumogastric through which branch irritation from the stomach may tend to bring about a disturbance of the vaso-motor control; in illustration of which irritation he instances a case of an elderly gentleman with no teeth who was in the habit of eating meat in very large pieces, and in whom a vertigo appeared which was at first deemed by the attending practitioner purely stomacic. For all practical purposes it was; but Woakes points out the fact, that, though the stomach was the real point of irritation, the vertigo was, accurately speaking, auditory. The patient was relieved by changing his diet. The obvious anatomical connection through which the labyrinthine pressure was altered in this case was the pneumogastric nerve, the inferior cervical ganglion, the vertebral artery, the basilar artery, the internal auditory artery. There are even more remote connections of this ganglion; for example, a branch connects it with the brachial plexus, through which path a severe rap on the so-called crazy bone may produce an attack of auditory vertigo. We should not forget in this connection the inhibitory nerve to the heart, whose intimate relations with the vaso-motor supply of the labyrinth accounts for the rapid fall, as a reflex preservative phenomenon. It has been suggested to me that the knock-out blow on the side of the neck, or even on the side of the jaw, may owe its disproportionate effect to this reflex train, though the immediate effect may be expended in the pneumogastric nerve.

This brief review will serve to bring to our notice the various directions from which an auditory vertigo may appear without disease of the ear. This brings us to the question Dr. J. J. Putnam has suggested; and I fully agree with him that an irritability of the centres of equilibration themselves is of the greatest importance in these cases. Given a case of no great irritability of those centres, there will be, of course, great resistance to a moderate degree of irritation, and *vice versa*. We see occasionally, for example, in cases of hysteria, without aural trouble, a typical auditory ver-

¹ See page 5 of the Journal.

tigo, a tendency to fall in a definite direction; still I do not believe it is entirely a question of irritability of equilibration in these cases, for in hysteria and in nervous prostration, vaso-motor disturbance is a not infrequent occurrence. Such patients are very liable, for instance, to flushes and chills, not to mention sudden edema. It seems, therefore, not improbable that such patients, on account of lack of vaso-motor control, may be subject to sudden alterations in labyrinthine pressure, tending to set up aural vertigo, in turn rendered more pronounced by central irritability.

DR. E. D. SPEAR: I don't know that I can add anything to the valuable paper which Dr. Blake has read this evening, except, perhaps, to emphasize, for the benefit of the general practitioner, the importance of examining the ear in all cases of obscure stomach affections, that is to say, those in which the symptoms, as nausea and vomiting, point to the stomach, because of this direct connection which the peripheral space organ, the utricle and semicircular canals have with the brain. The subject is one which few of us can go very deeply into on account of its intricacies, both anatomical and physiological. But the cases to which we should confine our attention to are those of middle-ear disease proper, in which the labyrinth is involved only by reason of contiguity, from direct or indirect pressure upon the stapes. The discussion of this question brings up to all of us numberless questions which we, perhaps, would not like to trouble Dr. Blake with. I may, perhaps, ask him what he considers the action of quinine on the auditory nerve, or whether he considers it a central affection or peripheral irritation. He made mention of the use of quinine in a case of aural vertigo, in which he gave very small doses. Perhaps it is on account of the usual fear of aurists of the effect of quinine, that we are cautious in its use. In small doses it is stimulating, in large doses toxic, though it is possible that we get a better effect in the use of quinine in these cases because of its antagonizing effect upon the hyperemia supposedly present.

Another interesting question which, of course, Dr. Blake did not touch upon in this connection, but which appeals to me, is the function of this portion of the auditory nerve in regulating the movements of the eyes in maintaining equilibrium. It is the question that comes to me frequently in the cases of vertigo I am called upon to look at, and in which I cannot find a cause within the ear sufficient to explain the continued duration of the vertigo after local treatment has had considerable effect upon it. In these cases there are to be found either errors of refraction possibly, or the so-called 'phorias of the oculists, that is, the divergencies due to changes of tension in the muscles of the eyes themselves.

DR. F. L. JACK: It is generally accepted that aural vertigo is due to increased pressure in the labyrinth on the vestibular and ampullar nerves. That must be true in nearly every instance; but a case occurs to me where vertigo was produced by exactly the opposite thing, that is, a diminution in the pressure in the vestibule. Of course, this could be demonstrated only in an operated case. I know of no other way of determining this fact. The case was one of a series experimented upon some few years ago by removing the stapes. This operation was done originally with the idea of improving the hearing; and after a few cases were operated upon, it occurred to me, after seeing a case with vertigo, that possibly removing the

stapes — which in some way might be pressing on the fluid and, in consequence, producing vertigo — would bring relief. It was found on attempt at extraction, that it was impossible, on account of bony fixation, to remove the ossicle. In the attempts at removal the arms of the stapes broke and the foot-plate was left firmly in place. It occurred to me then to make a perforation in through the foot-plate, and this was accomplished by means of a very small hook. The hook was easily passed through the foot-plate, and a discharge of fluid immediately followed. Attempts were made, by passing the hook into the hole, to break off the bone and draw it out. In doing the operation the foot-plate was not pressed in so as to increase the pressure, because in this pulling process the foot-plate was brought farther out, and by evacuating a few drops of fluid in the labyrinth, diminished any undue pressure there. The vertigo was increased very much, and it followed shortly after the operation before much of any swelling could possibly have taken place. In fact, there was no swelling or inflammatory reaction to be seen in the ear. The vertigo increased very considerably, continued a number of weeks, and slowly disappeared. I think this certainly is a case where the vertigo was made very much worse by a diminution in the pressure.

DR. CROCKETT: It seems to me there is one clinical point that might be elaborated a little, and that is that all cases that have fixation of the stapes or thickening of the membrane of the round window are much more liable to attacks of vertigo from changes of tension; and this has a clinical bearing in some cases which come to the aurist, the neurologist and to the general practitioner. It very often happens in the clinic that we see cases from other hospitals referred on account of vertigo where we find an old middle-ear thickening, and yet the stapes fixed or the round window fixed, and no apparent reason why the case should have vertigo at that time more than at any time in the last three, four or five years, perhaps; and very often I have found in this class of cases that the patient had some general disorder disturbing the arterial circulation, as chronic interstitial nephritis or chronic heart disease. It seems to me in this class of cases the aurist is too apt to be contented with finding the chronic thickening in the middle ear and not going further; and, of course, it is important in such cases to recognize the fact that the ear is only one factor in the general lesion, and it may be the first symptom of interstitial nephritis, or some similar disease disturbing the arterial tension. Of course, here treatment should be directed not to the ear particularly, because the ear has been in about the same condition a long time, but entirely to the general disease which is behind the vertiginous symptom.

DR. BLAKE: In answer to Dr. Spear's question, the quinine was given in this case, as in similar cases, in the small and continuous doses for its effect on the arterial tension, in accordance with the recommendation of recent French writers, and in consonance with experiments made in cases where the vertiginous symptoms were apparently due to nervous overstrain.

I am glad to hear Dr. Jack's case and to report a confirmatory observation. A young man, twenty-two years of age, had lost the membrana tympani, malleus and incus from the right ear as the result of a suppurative inflammation of the middle ear in childhood. Examination showed the tympanic mucous membrane

dry and transparent and the stapes in position, but without the attachment of the stapedius tendon; the hearing for the voice was practically nil in the right ear and very nearly normal in the left. The stapes was removed without difficulty by means of a short hook passed under its head, and came away without resistance and without other sensation to the patient than that of a slight snapping noise. The removal was followed by a slight and increasing congestion about the oval window, and within thirty seconds by a slight oozing of perilymph. The hearing was immediately improved; and the voice in an ordinary conversation tone was heard across the room, a distance of more than fifteen feet. Within five minutes the patient became violently dizzy, with a tendency to fall toward the right; and he was put to bed, where he remained forty-eight hours, during which time the vertigo gradually decreased. This experience was followed by variable hearing, with variations in the volume of discharge and occasional attacks of vertigo; but at the end of a week the discharge had ceased, the vertigo had disappeared, and the hearing had returned to its condition before removal of the stapes.

AMERICAN MEDICAL ASSOCIATION.

ABSTRACT OF THE PROCEEDINGS OF THE SECTION ON PRACTICE OF MEDICINE, PHILADELPHIA, JUNE 1-4, 1897.

(Continued from No. 25, p. 631.)

THE SERUM TEST FOR THE DIAGNOSIS OF TYPHOID.

THIS paper was read by DR. GERHARDT, of New York. He said the serum employed in the tests by the New York Board of Health was secured from blisters. The microscopic test was used whenever possible, while the macroscopic was seldom resorted to. Dilutions of one to ten were generally used, and cultures, eighteen to twenty-four hours old, and of great virulence, were used. The cultures were obtained from Pfeiffer. The distinctness of the reaction was more marked with virulent cultures. The medium might be agar or bouillon. The tests employed in the laboratory of the New York Board of Health were generally made with dry blood with a one to ten dilution and a fifteen-minute time-limit. If positive reaction is obtained from these tests, a positive diagnosis of typhoid is made; but if agglutination does not occur in fifteen minutes, or requires a greater dilution, a request for a further test with serum is always made. Others had suggested a dilution of one to thirty, or one to fifty, and a time-limit of two hours; but there did not appear to be any advantage in this procedure.

A CLINICAL REPORT ON SERO-DIAGNOSIS.

by DRs. J. H. MUSSER and JOHN M. SWAN, of Philadelphia, was read by Dr. Swan.

The tests were made with dried blood. One hundred tests were made. In nine the blood was taken from children under fifteen, and in the remainder from adults; twenty-six from females and seventy-four from males. Age and sex seemed to exercise no influence. The cases were divided into four classes: (1) typhoid fever during the disease, (2) during convalescence from typhoid, (3) where typhoid had been present at some time, and (4) where typhoid had not been diagnosed. In the latter, the reaction was ab-

sent in all cases, among which were cases of pneumonia, tuberculosis and catarrhal fever. His conclusions were: (1) that age and sex exercise no influence, (2) that the reaction might be obtained during the occurrence of the disease as early as the seventh day, (3) that the reaction disappeared at varying periods after the cessation of the disease, (4) that the reaction could not be obtained from blood taken from patients suffering from diseases other than typhoid.

DR. MARK W. RICHARDSON, of Boston, read a paper entitled

ELSNER'S METHOD OF DIAGNOSIS IN TYPHOID FEVER.

Elsner's gelatin-culture medium had first been prepared with carbolic acid; but, as a result of later experiments, he had been led to substitute potassium iodine, and the inoculation of this gelatin with the stools of typhoid fever had been very successful. No other bacteria than those of typhoid fever could be made to grow upon this medium. He had been led to examine this method of testing for typhoid fever partly from a desire to see whether it would confirm the tests made with the blood-serum, and partly to see whether it could be relied upon in those cases in which Widal's test failed to give a reaction. The result of his investigations convinced him that the serum test was preferable on account of its greater convenience in those cases where it gave a positive reaction; but cases in which the serum test had failed might show a typical reaction by Elsner's method. An examination of 29 cases other than typhoid showed no bacilli by Elsner's method, or the isolation of bacilli was imperfect. The statement made that the typhoid bacillus was a ubiquitous organism was not confirmed by this method, as the examination of the non-typhoid cases had failed to show the presence of the bacillus.

He summed up his conclusions by stating that the value of Widal's serum test was greater by reason of its simplicity, but a case which had failed to react to this method might still show the typical reaction if the stools were examined by Elsner's method.

DR. N. S. DAVIS, of Chicago, said that, according to his experience, 90 per cent. of cases of genuine typhoid gave a positive reaction to the Widal test, and in six per cent. there was a partial reaction. In three per cent. of cases there was no reaction whatever. The time at which the reaction could be obtained varied, and had no relation to the severity of the attack. In two and one-half per cent. of the cases with clinical diagnoses other than typhoid, a reaction was obtained, but in all of these cases there was a history of a prior attack of typhoid. In view of the fact that the reaction was not a constant attendant of typhoid fever, he suggested that it would be more correct to call it a symptom of typhoid fever, rather than a test for typhoid. It stood in the same category as rose-spots. When present with other symptoms of typhoid, these were of value. So it was with the serum test: it did not furnish conclusive evidence.

DR. H. A. WEST, of Galveston, Texas, said that the test promised to be of especial importance in his section of the country, and he hoped it would be the means of settling the vexed question of diagnosis between typhoid, malaria, continued fever, thermic fever, etc. Many of these fevers failed to respond to the salts of cinchona, and he was of opinion that such cases were typhoid in character, and it was to be hoped that this test would clear up the matter.

DR. J. B. HERRICK, of Chicago, gave the experience of Dr. George H. Weaver, of the Rush Medical College, in the diagnosis of typhoid fever by means of Widal's test. Several of the cases examined had all the symptoms of typhoid fever, and were also tuberculous, and in these the test failed to give a reaction. It was possible that this failure of the test was merely a coincidence, but it opened up the question whether this test was applicable in cases of mixed infection.

Immediately after the Section was called to order for the afternoon session, the following officers were elected for the ensuing year: Chairman, Dr. Fisk, of Denver; Secretary, Dr. Albert Jones, of Buffalo.

DR. A. P. OHLMACHER, of Cleveland, read a paper entitled,

OBSERVATIONS ON TWO EXAMPLES OF TYPHOID MENINGEAL INFECTION.

The author gave the clinical and pathologic aspects of the cases. The spleen weighed 220 grammes; the ileum was the seat of typical typhoid ulcers, and a hematoma was located in the brain substance. Cultures taken from the meningeal hemorrhage gave perfect growths of the typhoid bacillus.

The second case was like the first, but owing to lack of time Dr. Ohlmacher gave a brief synopsis of the two cases. Both gave clinical evidence of typhoid fever with suppurative leptomeningitis. Bacteriological investigation gave large numbers of typhoid bacilli and of no other micro-organisms, while an exhaustive investigation of other organs furnished undoubted evidence that the cases were true typhoid. In the second case there was broncho-pneumonia as a complication, and typhoid bacilli, as well as staphylococci, were demonstrated in the lungs. There was also endarteritis of the cerebral arteries.

The next paper was read by DR. WILLIAM OSLER, of Baltimore, entitled,

RELAPSES IN TYPHOID FEVER.

In 500 cases of typhoid fever treated in Dr. Osler's wards at the Johns Hopkins Hospital, there was a percentage of eight per cent. of relapses, about the same as that noted by Liebermeister, but a much larger percentage than that given by Murchison. Physicians were apt to shift the responsibility for relapses to errors of diet, but it was his experience that error in diet was not responsible in any considerable number of cases. The term "relapse" should be limited to those cases in which there were distinct evidences of reinfections after a period of apyrexia. Rise of temperature and return of dangerous symptoms, without a period of absolute freedom from fever and serious symptoms, should be regarded as an intercurrent relapse and not as a true relapse.

The sources of reinfection were as yet unknown, but a possible source was the lingering of the bacilli in the mucous membranes of the system. Chiari also made the interesting suggestion that the typhoid bacilli remaining in the gall-bladder might become the source of a secondary infection. In 19 out of 23 cases of typhoid fever, Chiari demonstrated typhoid bacilli in the gall-bladder. Relapses might be single, double, or rarely, triple. Several cases where there had been four or five relapses had been reported, and Dr. DaCosta stated that he had had a case with five relapses.

As illustrating the length of time a case of typhoid

fever might continue, he related the history of a case in which, after a period of six weeks' freedom from fever, a relapse occurred, and later, a second relapse; so that the original attack, with the two relapses, covered a period of six months. The relapses were not always of a similar character in their inception to the original attack, as the text-books used to teach. The fever did not increase by gradual steps, as the original fever did, but, on the contrary, might go up with two or three short bounds. In other cases the relapse might be the counterpart of the original attack. He did not believe that the Brand system of treatment had anything to do with the occurrence of relapses. The Brand method was used extensively in the wards of the Johns Hopkins Hospital, and the proportion of relapses there was not excessive, and no one could say, from a study of those records, that hydrotherapy had anything to do with such occurrences.

PERICHONDritis OF THE LARYNX IN TYPHOID FEVER.

was the title of the next paper, read by DR. M. H. FUSSELL, of Philadelphia.

The case of which this paper was a report occurred in a man thirty years of age, who came under his observation in December, 1894. There was considerable hoarseness, and the patient afterward developed pneumonia. After eating an apple he was seized with stenosis, and an examination showed an edema of the larynx. Perichondritis of the larynx was diagnosed, and tracheotomy was suggested, but the patient refused to have the operation done. He died on the seventh day, and the autopsy showed that there was a large perichondrial abscess. Hoarseness, with respiratory distress, were the only symptoms complained of. The complication was very infrequent, but its infrequency did not excuse physicians and writers for neglecting it. The only treatment was tracheotomy.

DR. H. A. WEST, of Galveston, read a paper upon

THE RATIONAL ANTISEPTIC TREATMENT OF TYPHOID FEVER.

He was sceptical of the value of the so-called abortive treatment of typhoid, believing, as he did, that this was a self-limited disease. Nor did he believe in the efficacy of the antiseptic treatment, for before the disease attained its height the bacilli would have passed through the intestinal tract into the blood, and no drug known could reach them there. His experience with the various "cures" recommended had not been such as to commend them to his judgment. The rational treatment of typhoid—the only antiseptic treatment—"begins at the mouth and ends at the bedpan." The way to give antiseptics was to withhold anything in the way of food or medicines that would require any antiseptics, and to use the tooth-brush frequently for the dislodgement of particles of food that, accumulating in the teeth, might decompose and cause fermentation. One of the chief difficulties in the treatment of typhoid was the gastric disturbance, which was generally a complication, for in no disease, except cancer of the stomach, was the power of the stomach to digest food so weakened as in typhoid fever. In typhoid fever the stomach might lose half its bulk. Added to this decrease in the amount of gastric juice, there was also a decreased secretion in hydrochloric acid. For these reasons we should abstain from loading down the stomach with solid food

which it could not dispose of, and the condition should be treated by the administration of pepsin, hydrochloric acid, and the like, which, in this case, were antiseptics in the proper sense of the word. It was now proved that the typhoid bacilli left the mucous membrane of the intestinal canal in the early stages of the disease and entered the blood, so that the administration of antiseptic drugs could have no effect upon them. In the rational treatment of the disease was included a plentiful supply of water to flush out the stomach; and good results follow copious irrigations of the large intestine.

The next paper read was by Dr. J. N. URSHUR, of Richmond, Va., upon

THE TREATMENT OF TYPHOID FEVER.

The author went into details as to the method of disinfecting bedpan, bed-clothes, keeping the patient clean, etc. He deprecated the use of alcohol in the early stages of the disease, except in the cases of persons accustomed to its use. He said that the headache required no treatment, as it would disappear spontaneously in the second week. Phenacetin might be used with caution, but in general the use of the coal-tar derivatives should be avoided. Bromide of soda should be given for insomnia; and for coma vigil there was nothing that could take the place of opium. Somnolence should be treated with alcohol. Nausea and vomiting were rarely of sufficient severity to require treatment, but when present, drop doses of the tincture of iodine were useful. Constipation was not an indication of grave intestinal lesions, and laxatives should be avoided. Salol should be administered when the stools were offensive, and sordes called for the internal use of turpentine. Strychnine with nitro-glycerin should be given for a weak heart. Peritonitis demanded treatment with tincture of opium, or hypodermic injections of morphine. Laparotomy was not justifiable, for the reason that the probability of saving the patient was very slight. The bladder should be emptied freely, either naturally or by means of the catheter.

The speaker considered the abortive and antiseptic treatments in vogue as being irrational. He had never tried the Woodbridge treatment, because he regarded his patients as of too much consequence to be subjected to such danger. With his knowledge of the disease and of its self-limited character, he could not understand the wonderful results claimed for the treatment by Dr. Woodbridge, unless the age of miracles had returned. The testimonials which had been filed regarding the efficacy of the treatment were of no more value than similar testimonials for some "cancer cure" or "kidney cure," and other such cures.

THE USES OF THE X-RAY IN MEDICINE

were enumerated by Dr. FRANCIS H. WILLIAMS, of Boston. Charts were exhibited by him showing the results of investigations by the x-ray in cases of pleurisy, pneumonia, tuberculosis and emphysema; and during his discussion of the subject Dr. Williams said in substance:

Probably many will wish to know whether I have found x-ray examinations harmful, and whether useful in practical medicine. No harm or inconvenience has followed their use in more than 500 examinations I have made during the past year. They are useful to

the physician if he is provided with good apparatus. The varying resistance which the different tissues of the body offer to the passage of the x-ray depends upon difference in bulk and in chemical composition. Organic substances made up of carbon, hydrogen and nitrogen allow the rays to pass readily, while those like bone, containing an inorganic substance like calcium, offer more resistance to the rays.

The difference in permeability of air and water by the x-rays is a very important factor in their usefulness in thoracic diseases. In pulmonary tuberculosis the fluoscope may suggest disease, first, by showing a diminution in the volume of the diseased lung by the position and movements of the diaphragm; second, by showing an increase in density by diminution in the normal brightness. The lung may become so dense that no more rays pass through it than through the liver. The brightness in the lungs indicates the amount of air that enters the body.

I have examined more than 75 cases of tuberculosis with the fluoscope, and found that in certain cases this instrument showed that the disease was more extensive than the usual physical examination indicated; in other words, it showed increase in density in the lungs earlier than was detected by the physical examination. We can detect an abnormal condition of the lungs in cases of tuberculosis earlier by means of the fluoscope than by auscultation and percussion.

I have examined more than 50 cases of pneumonia with the fluoscope.

In concluding, Dr. Williams spoke of the beneficial effects of fluoroscopic examinations in cases of heart trouble, pleurisy and other maladies.

The paper read by Dr. C. L. LEONARD, of Philadelphia, was upon

THE APPLICATION OF THE RÖNTGEN RAYS TO MEDICAL DIAGNOSIS.

His methods were practically similar to those advocated by Dr. Williams. Illustrations of Röntgen-ray experiments were exhibited.

(To be continued.)

Recent Literature.

Ptomaines, Leucomaines, Toxins and Antitoxins; or, The Chemical Factors in the Causation of Disease. By VICTOR C. VAUGHAN, Ph.D., M.D., and FREDERICK G. NOVY, Sc.D., M.D. Third edition, revised and enlarged. Philadelphia and New York: Lea Brothers & Co. 1896.

This book aims at being a concise collection of facts and observations on the above subject. It contains chapters on the bacterial poisons contained in foods, on the examination of foods for poisonous substances, on the chemistry of the infectious diseases and on the subjects connected with the germicidal and antitoxic properties of the blood serum. The chemistry of the ptomaines and leucomaines and the methods of isolating toxins are discussed in other chapters. The book is largely a compilation, and shows little effort on the part of the authors to digest the great mass of material which they have used, so that in places it is very heavy reading. As a compilation, however, it may be found useful for reference.

The publisher's part has been well done.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JULY 1, 1897.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

MEDICAL MEN AND THEIR HEALTH.

At this season when so many other portions of the community are planning vacations, relaxation, shorter working-hours, it is well that the doctor, who spends all the rest of the year caring for the health of others, should take stock of his own and consider whether he is sufficiently solicitous for improving, or at least for keeping good, his own physical condition, for there is no laborer in any walk of life for whom such care is more essential.

Under the above head, Dr. John W. Teale, in the *Lancet*, offers some useful suggestions which physicians would do well to ponder. In response to a hypothetical question, "What will most conduce to the success of a general practitioner?" he replies, "Power of concentration and command of temper."

By power of concentration he would mean that power by which a man, however wearied, on entering a house is able at once to abstract his brain from everything that has already happened, and to concentrate his mental faculties on the case that is before him. Patients are naturally somewhat selfish and are very quick to observe if they do not get full attention, and if, when the finger is on the pulse, the mind is not on the patient.

Secondly, command of temper. To the quick, high-strung, sensitive man, exhausted by the worry and anxiety of daily life, thorough command of temper with testy, querulous, exacting patients can only be obtained by rigid self-control commenced in early life. To be forever bearing in mind that the patient is the sufferer, that testiness and ill-temper are due to physical weariness and distress, and not to disloyalty to the doctor, is a task that will try the strongest nature.

In order to cultivate and obtain this concentration and command of temper, the physician should live as far as possible a simple out-door life in constant physical training. "Why," he asks, "should a man become stout and short of wind because he has reached fifty?"

Simply because he is struggling with his life work when his physical condition is not fit to grapple with it.

The exercises which Dr. Teale recommends are performed with light Indian clubs; these or with dumb-bells or the ordinary parlor gymnastics, constitute a kind of training which students are apt to drop when they leave college, but which can profitably be kept up during the whole life. It may be said that many medical men do not need these exercises, their physical powers being sufficiently tested every day on their bicycle and in other ways. Some in the country do a little at sawing or splitting wood in the morning to keep themselves in trim. It is a mistake to suppose that the busy man wants a great deal of physical exercise. His ordinary day's work, with what it involves in taxing mind and body, is generally enough for him. One writer, moreover, suggests that it is well for the physician to cultivate the art of sleeping for a few minutes at any time. A man can only live safely on the interest of his vital strength. Any withdrawal of principal should be promptly replaced.

Dr. Teale advises that two good meals and one moderate one be taken each day, and thinks that a late dinner is preferable, for if taken in the middle of the work, either the meal or the patients must suffer. It is possible to be too busy to dine, in which event a cup of soup, or a sandwich and a glass of wine is better than a hearty meal. A good dinner implies leisure for digestion. Half an hour's leisure before dinner will often enable a man to eat a hearty meal. Everything that is good is wholesome, taken at proper times and in proper quantities. After a man is twenty-five or thirty, he only wants as much food as will maintain his weight and not add to it.

Like St. Paul he believes in a little wine, taken diluted at meals (provided it be good wine)—some good people will resent this advice—and thinks that spirits are useful when one is jaded and exhausted, but are unnecessary and hurtful when taken between meals or at bedtime, except for special reasons. "Three hundred and sixty-five glasses of whiskey taken in one year at bedtime are an unnecessary and a severe tax on the liver when its work is in full swing."

With regard to baths, an ordinary healthy man may take a cold bath daily almost up to any age; but as the object is not only to get up a reaction but to keep it, most hardworking men require that cheapest of all luxuries, a fire in the dressing-room and a hot bath-towel. If this is followed by a course of Indian clubs in his flannels, a man will be fit to face any weather. The same underclothing should be worn summer and winter, of wool, and only the outer clothing varied. This advice is better suited to England than to New England. Colds are generally caught either in ill-warmed rooms or through ill-protected feet. "If chilled through by a cold drive, walk home, if possible, the last mile or two, keeping on your heavy wraps to restore your circulation. . . . Light your fire whenever you can endure it; it is the cheapest and best

health-giver in the world, especially in cold, thundery weather in the summer; with a well-arranged room and a proper fire-place most healthy people can learn to sleep with their windows open, winter and summer."

Dr. Teale cautions against badly aired beds, and says, "the risk will be best guarded against by carrying in the travelling-bag a light flannel dressing-gown to put on the damp sheets."

With regard to turning out of bed at night, no amount of precaution can make this otherwise than dangerous. But if an arrangement can be made by which the clothes can be kept aired and warm, and a cup of hot milk with a teaspoonful of brandy can be procured, the risks can be reduced to the minimum.

There is a timely word about holidays. Every medical man, if possible, should have an out-door sport of some kind: golf and cycling are good, but perhaps the best is fly fishing. It takes one usually into a beautiful country, the exercise is gentle and varied, the interest absorbing, and it is better for the jaded practitioner than scampering half over Europe in a hurry in a second-class railway carriage in charge of a party of tourists.

Much of the above is what judicious medical advisers are constantly telling their patients; but it is not amiss that somebody should tell it to the medical advisers themselves. The doctor is apt to have less attention paid him, whether sick or well, than any one else.

DOLICHOCEPHALY AND TUBERCULOSIS.

At a meeting of the New York County Medical Association held June 21st, Dr. Mark I. Knapp read a paper in which he advanced the novel idea that a short bi-parietal diameter of the cranium is a positive and diagnostic characteristic of tuberculosis. He said that he did not claim that all persons with long, narrow heads suffered from the disease, but did maintain that all such had a predisposition to it. Moreover, that whenever such a person was not well, it would be found, provided there was not an excess of urates in the urine, that he was suffering from tuberculosis, either of the lungs or some other portion of the body. In 477 out of 484 cases of tuberculosis examined by him in the City and other hospitals, he found the narrow bi-parietal diameter present.

A remarkable conclusion arrived at by Dr. Knapp from his study of the subject was, that tuberculosis is not an infectious disease; it being demonstrated, in his opinion, that unless an individual has the shape of head predisposing to it, he is in no danger of contracting tuberculosis, however much he may be exposed to it.

Shall boards of health segregate dolichocephalics, males and females separately?

It has remained for an end-of-the-century physician to demonstrate that to be long headed, which has heretofore been considered desirable, is really unsafe. Perhaps as long-headed people are susceptible to long micro-organisms or bacilli, round-headed or brachy-

cephalic individuals may be susceptible to infection with round organisms or cocci. Perhaps Dr. Knapp can establish such a connection.

MEDICAL NOTES.

BERI-BERI AT SANTIAGO.—Beri-beri is reported to be very prevalent at this port.

DEATH OF FATHER KNEIPP.—Father Kneipp, of water-cure fame, whose death has been so many times falsely reported of late, actually died on June 17th, at the age of seventy-six.

JUBILEE HONORS.—Sir William MacCormac, President of the Royal College of Surgeons, and Dr. Samuel Wilks, President of the Royal College of Physicians, were created baronets at the Jubilee Celebration, and they were the only medical men honored.

COLORADO'S CONTRIBUTION TO THE RUSH MONUMENT FUND.—Colorado has already fulfilled the pledge for a two-thousand-dollar contribution to the Rush Monument Fund, made by Dr. Graham at the meeting of the American Medical Association at Philadelphia. At the meeting of the State Medical Society June 15th, the full sum pledged by Dr. Graham was immediately raised by individual subscriptions offered most generously and with great enthusiasm.

TRANSPORTATION OF A LEPER.—A case of leprosy was recently discovered in Johns Hopkins Hospital, in the person of a Mrs. Sansoni, who was found to have recently arrived from Allegheny City. In spite of the protest of that city, the Baltimore officials are going to send her back in a steel freight-car which is to be sealed until its arrival. Perhaps it would be well to disinfect the railroad track with bichloride after the passage of the car, in order to avoid all possibility of infection of the passengers in other trains.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, June 30, 1897, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 85, scarlet fever 35, typhoid fever 8.

THE HARVARD DENTAL ALUMNI ASSOCIATION held its Twenty-Sixth Annual Dinner at Young's Hotel on Monday evening, June 28th. At the preceding business meeting officers were elected as follows: President, Dr. Joseph T. Paul, Boston; Vice-President, Dr. Frederick Bradley, Newport, R. I.; Secretary, Dr. Waldo E. Boardman; Treasurer, Dr. H. S. Parsons; Executive Committee, Drs. Waldo E. Boardman, William P. Cooke, Frank T. Taylor; Council, Drs. Joseph T. Paul, Frederick Bradley, H. S. Parsons, Waldo E. Boardman, William P. Cooke and Frank T. Taylor. After the dinner, which was attended by a large number, the Rev. Dr. Hodges, Dean of the Episcopal Theological School at Cambridge, addressed the company. Dr. Eugene H.

Smith, Dean of the Dental School, gave some interesting facts and figures in regard to the school. He was followed by Dr. Thomas Fillebrown and Dr. Charles W. Berry.

HARVARD MEDICAL ALUMNI ASSOCIATION.—This Association held its Seventh Annual Meeting on Tuesday, June 29th, at the Harvard Medical School, the President, Dr. George B. Shattuck, in the chair. The following officers were elected: President, David W. Cheever, M.D., 1858, Boston; Secretary, James S. Stone, M.D., 1894, Boston; Councillors for the term ending 1901, George B. Shattuck, M.D., 1869, Boston, Charles F. Folsom, M.D., 1870, Boston, Joseph E. Garland, M.D., 1877, Gloucester, Mass.

The following resolution, proposed by Dr. L. R. Stone, of Newton, Mass., was unanimously and enthusiastically adopted:

That the President of the Association be authorized in behalf of the Association to petition the Board of Overseers to further consider the question of extending the right of voting for members of the Board of Overseers to graduates of the Medical School.

Dr. Francis P. Kinnicutt, of New York, Professor of Clinical Medicine in the Medical School of Columbia College, was elected an honorary member of the Association. The reports of the Secretary and Treasurer were read and accepted. After the adjournment of the business meeting, the annual dinner took place at the Hotel Vendome. More than two hundred members and guests were present. After dinner, the President, Dr. George B. Shattuck, President Eliot, Dr. J. M. Da Costa, of Philadelphia, Drs. F. P. Kinnicutt, and J. W. Brannan, of New York, Dr. F. M. Spalding, of Cambridge, and the President-elect, Dr. Cheever, addressed the company. Dr. S. W. Driver, of Cambridge, read the report for the Committee on the Medical School.

POUGHKEEPSIE CLIMATIC EFFECTS.—Probably the change of climate from the seashore to the more relaxing and debilitating atmospheric conditions at Poughkeepsie had much, though not all, to do with the collapse of the Harvard crew in the late University boat race. An exposure of three weeks to such a change is either too long or not long enough.

THE SUPREME COURT SUSTAINS THE BOARD OF REGISTRATION IN MEDICINE.—Judge Morton has denied the petition of Dr. Charles Zieman to the Suffolk Supreme Court for a writ of mandamus to compel the Board of Registration in Medicine to issue to him a certificate to authorize him to practise as a physician. Dr. Zieman, who has an office in South Boston, claimed he had practised medicine in this State three years continuously before the act requiring physicians to be registered went into effect, which was in 1894, and was therefore entitled to a certificate without taking an examination. The Board refused to grant him a certificate upon such premises. The evidence at the hearing failed to establish his claim that he had practised in the State three years before 1894.

CENTENNIAL ANNIVERSARY OF DARTMOUTH MEDICAL SCHOOL.—The one hundredth anniversary of the Dartmouth Medical School was observed by exercises in the college church at Hanover on June 29th. President Tucker presided, Dr. Phineas S. Connor, 1861, of Cincinnati, O., gave an historical address. At the conclusion of the address there was a banquet of the medical men at Butterfield Museum.

NEW YORK.

YELLOW FEVER AT QUARANTINE.—The steamship *Finance* which left Colon on June 14th arrived at Quarantine on June 21st with yellow fever on board. It was found that one of the passengers had been attacked with the disease on the 15th, and two others on the day following. Two of them died at sea, and the third just as the vessel came to anchor. When Health Officer Doty boarded the *Finance* he found that three other passengers were down with yellow fever. They were transferred to the hospital on Swinburne Island, and all the other passengers sent to Hoffmann Island for detention and observation.

RECOVERY WITH A BULLET IN THE BRAIN.—A son of Police Captain Schmittberger, who was accidentally shot in the head at a church fair on May 26th was discharged from the Mount Sinai Hospital on June 20th, with the pistol bullet still lodged in the brain. He has recovered with the exception that the entire right side of the body is paralyzed from the injury caused to the motor tract in the left cerebral hemisphere.

THE BROOKLYN WATER-SUPPLY.—The Brooklyn Department of Public Works has recently made public the report of Prof. Albert R. Leeds's examination of the water-supply of Brooklyn, together with the statement of Chief Engineer De Varona. Dr. Leeds states that the well-remembered trouble with the water last summer was due to the presence in it of a form of algæ known as the asterionella, which is enclosed in an envelope of silica and secretes an oil of a fishy and salty flavor. These algæ derive their nourishment from silica, which is particularly abundant in the Brooklyn water; so that the same difficulty may be looked for again as long as the same physical conditions as at present exist. The enormous multiplication of the algæ is favored by plenty of light, by a gentle tremulous motion of the water, by the absence of peaty coloring matter in the water, and by its storage in shallow reservoirs. Dr. Leeds recommends that the storage reservoir should be converted into a substantially subterranean basin, necessitating the use of "by pass" pipe. Engineer De Varona states that the cleansing of the ponds and streams suggested by the Health Department, while good in itself, did not reach the source of the trouble. He urges the building of the "by pass" pipe around the Ridgewood reservoir, and mentions that the same trouble with the water at Brookline, Mass., was remedied by the building of a covered reservoir, thus excluding the light necessary to the existence of this form of plant life.

Miscellany.

STUDY OF THE AMERICAN MEDICINAL FLORA.

We have received from Dr. H. H. Rusby, Chairman of the General Commission, whose address is the New York College of Pharmacy, and Dr. Valery Harvard, Chairman of the Sub-Commission, address, Fort Slocum, Davids Island, New York, a statement in regard to the above subject.

The Sub-Commission of the Pan-American Medical Congress appointed to study the medicinal plants of the United States has entered into an association with the Smithsonian Institution for that purpose. The attention of our readers is called to the respective circulars issued by these organizations, which we print below.

SMITHSONIAN INSTITUTION,
WASHINGTON, D. C., May 28, 1897.

DEAR SIR:—The Smithsonian Institution has undertaken to bring together all possible material bearing on the medicinal uses of plants in the United States. Arrangements have been made with a body representing the Pan-American Medical Congress, the Sub-Commission on Medicinal Flora of the United States, to elaborate a report on this subject, and the material when received will be turned over to them for investigation.

The accompanying detailed instructions relative to specimens and notes have been prepared by the Sub-Commission.

All packages and correspondence should be addressed to the Smithsonian Institution, Washington, D. C. and marked on the outside *Medicinal Plants, for the U. S. National Museum*.

Franks which will carry specimens, when of suitable size, together with descriptions and notes, free of postage through the mails, will be forwarded upon application. Should an object be too large for transmission by mail, the sender is requested, before shipping it, to notify the Institution, in order that a proper authorization for its shipment may be made out.

Respectfully,

S. P. LANGLEY, *Secretary*.

INSTRUCTIONS RELATIVE TO MEDICINAL PLANTS.

The Pan-American Medical Congress, at its meeting held in the City of Mexico in November, 1896, took steps to institute a systematic study of the American medicinal flora, through the medium of a General Commission and of special Sub-Commissions, the latter to be organized in the several countries. The Sub-Commission for the United States has been formed and consists of Dr. Valery Harvard, U. S. A., Chairman; Mr. Frederick V. Coville, Botanist of the U. S. Department of Agriculture; Dr. C. F. Millspaugh, Curator of the Botanical Department of the Field Columbian Museum, Chicago; Dr. Charles Mohr, State Botanist of Alabama; Dr. W. P. Wilson, Director of the Philadelphia Commercial Museums; and Prof. H. H. Rusby, of the New York College of Pharmacy. This Sub-Commission solicits information concerning the medicinal plants of the United States from every one in a position to accord it. The principal points of study are as follows:

1. Local names.
2. Local uses, together with historical facts.
3. Geographical distribution and degree of abundance in the wild state.
4. Is the plant collected for market, and if so,
 - (a) At what season of the year?
 - (b) To how great an extent?
 - (c) How prepared for market?
 - (d) What is the effect of such collection upon the wild supply?
 - (e) What price does it bring?
 - (f) Is the industry profitable?
5. Is the plant, or has it ever been, cultivated, and if so give

all information on the subject, particularly as to whether such supplies are of superior quality, and whether the industry has proved profitable.

6. If not cultivated, present facts concerning the life history of the plant which might aid in determining methods of cultivation.

7. Is the drug subjected to substitution or adulteration, and if so, give information as to the plants used for this purpose.

While it is not expected that many persons will be able to contribute information on all these points concerning any plant, it is hoped that a large number of persons will be willing to communicate such partial knowledge as they possess.

It is not the important or standard drugs alone concerning which information is sought. The Sub-Commission desires to compile a complete list of the plants which have been used medicinally, however trivial such use may be. It also desires to collect all obtainable information, historical, scientific and economic, concerning our native and naturalized plants of this class, and, to that end, invites the co-operation of all persons interested. Poisonous plants of all kinds come within the scope of our inquiry, whether producing dangerous symptoms in man, or simply skin inflammation, or, as "loco-weeds," deleterious to horses, cattle and sheep. In this respect, the general reputation of a plant is not so much desired as the particulars of cases of poisoning actually seen, or heard from reliable observers. It is believed that much interesting knowledge can be obtained from Indians, Mexicans and half-breeds, and that, consequently, Indian agencies and reservations are particularly favorable fields for our investigation. Such knowledge will be most acceptable when based upon known facts or experiments.

In order to assist in the study of the habits, properties and uses of medicinal plants, the Sub-Commission undertakes to furnish the name of any plant-specimen received, together with any desired information available.

Owing to the diversity in the common names of many plants, it will be necessary for reports, when not furnished by botanists or others qualified to state the botanical names with certainty, to accompany the same with some specimens of the plant sufficient for its identification. While the Sub-Commission will endeavor to determine the plant from any portion of it which may be sent, it should be appreciated that the labor of identification is very greatly decreased, and its usefulness increased, by the possession of complete material, that is, leaf, flower and fruit, and in the case of small plants, the underground portion also. It is best to dry such specimens thoroughly, in a flat condition under pressure, before mailing. While any convenient means for accomplishing this result may be employed, the following procedure is recommended. Select a flowering or fruiting branch, as the case may be, which when pressed shall not exceed 16 inches in length by 10 inches in width. If the plant be an herb two or three feet high, it may be doubled to bring it within these measurements. If it possess root leaves, some of these should be included. Lay the specimen flat in a fold of newspaper and place this in a pile of newspapers, carpet felting, or some other form of paper which readily absorbs moisture, and place the pile in a dry place under a pressure of about 20 to 30 pounds, sufficient to keep the leaves from wrinkling as they dry. If a number of specimens are pressed at the same time, each is to be separated from the others by three or four folded newspapers or an equivalent in other kinds of paper. In 12 to 24 hours these papers will be found saturated with the absorbed moisture, and the fold containing the specimen should be transferred to dry ones. This change should be repeated for from two to five days according to the state of the weather, the place where the drying is done, the fleshiness of the specimens, etc. The best way to secure the required pressure is by means of a pair of strong straps, though weights will do. The best place for drying is beside a hot kitchen-range. When dry, the specimens should be mailed between cardboards or some other light but stiff material which will not bend in transit.

It is a most important matter that the name and address of the sender should be attached to the package, and that the specimens, if more than one, should be numbered, the sender retaining also specimens bearing the same number, to facilitate any correspondence which may follow. The Sub-Commission requests that, so far as practicable, all plants sent be represented by at least four specimens.

Correspondence.

THE ACCIDENTS PRODUCED IN SERO-THERAPEUTICS.

BOSTON, June 15, 1897.

MR. EDITOR:—No matter what may be the nature or composition of the various serums now employed in medicine, the accidents they occasion have in most instances been identical in nature.

The anti-diphtheritic serum has produced the following: (1) Abscesses, that might be considered as accidental when only one occurs; but Sevestre and Variot have placed on record epidemics of abscesses, of no great seriousness be it said, but which must be accounted for by an alteration of the product employed. (2) Certain exanthemata occurring in varying proportions, attaining the high figures of 50 per cent. of cases according to McCrombie, but more usually in about 13 to 15 per cent. (3) Arthropathies, often coexisting with the cutaneous phenomena and subsiding when the skin manifestations disappear; and in 1895 reports from Germany put the joint complications as occurring in about 1.5 per cent. of cases. (4) General complications, such as albuminuria, urobilinuria, peptonuria, epistaxis and metrorrhagia. (5) During the course of the post-diphtheritic syndrome, vomiting, diarrhea, inflammation of the lymphatic glands, tumefaction of the spleen and cardiac disturbances (such as arrhythmia, tachycardia, *bruit de galop* and edema of the limbs) have been observed at the same time that the cutaneous and joint complications were present. And, lastly, let us mention those cases of death which have been quite often observed whose cause could not be exactly explained.

Anti-streptococcus serum has produced urticaria, erythema and inflammation of the joints, as well as patches of erysipelas at the point of inoculation. In the case of a little girl of ten years afflicted with a membranous tonsillitis, Variot employed this serum, with the result that the accidents produced by it were far more serious than the primary affection.

It is most probable that in such cases the bacteria are still living in the serum. Roger, of Paris, has prepared an anti-streptococcus serum, 300 c. c. of which he injected into a female suffering with puerperal septicemia, and which cured the patient without any complications taking place.

The serums obtained from the dog, goat, lamb and calf, the anti-tetanus serum, and Maragliano's serum all have their series of complications, which, by their behavior and aspect recall those produced by the anti-diphtheritic serums.

The sero-therapeutics for variola demands a more special mention and description. Here we are not dealing with a product requiring only from one, two, or even twenty to thirty cubic centimetres for each injection, but a fluid injected in large quantities. Bèclère injected 1,560 c. c. of serum, taken from a vaccinated cow, in a female suffering with confluent small-pox; the patient recovered without any complication, excepting a slight exanthema situated over the internal aspect of the knees, the right thigh and under the right breast. Fourteen former cases and other recent observations have demonstrated the harmlessness of massive injections in man. Nevertheless, Bèclère has observed inflammation of the joints and in one case very serious complications.

The only serum whose use has never been known to produce any complications when injected into man, is human serum.

Many and varied are the explanations given to account for post-sero-therapeutical complications. Legendre considers that the serum of certain horses, and not the antitoxin, is to blame. Lebreton, Magdeleine and Variot are also of this opinion, but believe that the serum itself must be taken into consideration as well.

Latent microbism, awakened into activity by the laceration of the connective-tissue meshes produced by the injection, is also a theory upheld by Legendre. Sevestre is more inclined to believe that the serum is harmless, and that it is to the antitoxin that we must attribute the complications. Marville, d'Astros and Engelhardt have reported cases that would appear to show that the reactions of the temperature are in all probability due to individual predispositions.

After the fatal cases reported by Guinon and Moizard, Sevestre attributed the factors of the concomitant or added infections as the cause and more especially the streptococcus, but Netter does not accept this theory and believes that the substance giving rise to the complications is an element pre-existing in the serum of certain animals and that only at certain given times.

Now, if the antitoxins could be incriminated, the number of exanthemata would naturally be proportional to the quantity of serum injected, and it is a fact that the majority of writers attest that the skin manifestations are more infrequent the greater the antitoxic quality of the serum and consequently requiring a small amount of liquid for each injection. The writings of Zagari and Calabresse, confirmed by those of Poix, distinctly prove that anti-diphtheritic serum has an inferior toxic power to that taken from a normal horse.

There now remains the serum itself, whose toxicity has been shown to be at least equal to that of medicated serums. The harmful qualities of serums are not constantly present and are usually observed in series, and it is not of infrequent occurrence to observe long periods of time during which none of the complications are reported as appearing in cases under serum treatment.

If the vehicle is the cause of complications and if the decrease in its quantity in no way attenuates its efficacy, it is quite natural to endeavor to extract the curative principle from the antitoxic serums.

In Germany, quite recently they have been able to precipitate the antitoxins of tetanus and diphtheria in the serums; but on account of an absolute want of experiments and precise knowledge of the therapeutic value of these precipitates they leave us, for the present, at least, in the dark as to their use.

Very truly yours,

C. G. CUMSTON, M.D.

HOSPITAL AND DISPENSARY ABUSE.

A CORRESPONDENT writes us as follows, with regard to this subject. His words portray vividly the manner in which hospital abuse bears upon many young and struggling members of the medical profession.

MR. EDITOR:—The abuse of medical charity is a matter of vital importance to a great portion of the profession—probably a greater portion than one can imagine. Although one of the thousands of sufferers, I try to view the matter from an impartial point of view, my only desire being to stimulate a discussion of this most important problem. I am neither a "calamity-howler," nor a prophet; but as far as I can see in the future, the time is not far distant when the Massachusetts Medical Society will be compelled to take a hand in this matter, or legislative interference will be called to aid. No words of mine (young, poor, insignificant practitioner, that I am) can be strong enough in condemnation of the system of "charitable anarchy," that deliberately, without any necessity therefor, deprives great numbers of practitioners of the legitimate means for earning a livelihood.

I assure you, sir, these are not phrases, but plain, simple, unvarnished truths. Yours truly, JUSTICE.

METEOROLOGICAL RECORD

For the week ending June 19th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Newburyport	14,794	—	—	—	—	—	—	—
Amesbury	10,920	—	—	—	—	—	—	—

Deaths reported 3,150; under five years of age 1,141; principal infectious diseases (small-pox, measles, diphtheria and croup, whooping-cough, erysipelas, diarrheal diseases and fever) 427, consumption 361, acute lung diseases 301, diarrheal diseases 165, diphtheria and croup 139, scarlet fever 26, measles 25, typhoid fever 20, cerebro-spinal meningitis 16, whooping-cough 15, erysipelas 9, malarial fever 8, small-pox 4.

From measles New York 6, Brooklyn 5, Chicago 4, Philadelphia, Baltimore and Providence 2 each, Boston, Fall River, Lowell and New Bedford 1 each. From typhoid fever Chicago 6, New York and Boston 3 each, St. Louis and Baltimore 2 each, Cincinnati, Lawrence, Taunton and Waltham 1 each. From cerebro-spinal meningitis Boston 6, New York and Washington 3 each, Baltimore, Somerville and Chelsea 1 each. From whoop-

ing-cough Brooklyn and St. Louis 3 each, Chicago, Baltimore and Washington 2 each, New York, Boston and Lawrence 1 each. From erysipelas New York 4, Philadelphia 2, Chicago, Lawrence and Chelsea 1 each. From malarial fever Philadelphia 6, New York 2. From small-pox New York 3, Cambridge 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,992,524, for the week ending June 12th, the death-rate was 15.6. Deaths reported 3,297; acute diseases of the respiratory organs (London) 191, measles 131, whooping-cough 90, diphtheria 57, diarrhea 48, scarlet fever 28, fever 24.

The death-rates ranged from 8.2 in Croydon to 23.7 in Salford; Birmingham 19.8, Bradford 16.5, Cardiff 13.2, Hull 15.5, Leeds 15.9, Leicester 14.1, Liverpool 21.1, London 13.8, Manchester 20.3, Newcastle-on-Tyne 17.5, Norwich 12.8, Nottingham 16.1, Portsmouth 14.9, Sunderland 17.6, Swansea 12.0.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 19, 1897, TO JUNE 25, 1897.

Leave of absence for three months, to take effect about July 1, 1897, with permission to go beyond sea, is granted COLONEL WILLIAM H. FORWOOD, assistant surgeon-general, U. S. A.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE TWO WEEKS ENDING JUNE 26, 1897.

E. Z. DERR, surgeon, ordered to duty with new Naval Rendezvous, New York.

J. F. URIC, passed assistant surgeon, detached from Rendezvous, Boston, June 24th, and ordered to the "Wabash" same day.

F. B. STEPHENSON, surgeon, detached from the "Wabash," June 24th, and ordered to Marine Rendezvous, Boston, same day.

W. B. GROVE, assistant surgeon, ordered to the Naval Laboratory, New York, June 21st.

L. W. SPATLING, passed assistant surgeon, ordered to the Naval Hospital, Norfolk, July 1st.

G. B. WILSON, passed assistant surgeon, detached from the "Yaotie," ordered home and granted two months' leave.

INTERNATIONAL MEDICAL CONGRESS.

RAILWAY TICKETS AND PASSES.

A letter from the Secretary-General of the Twelfth International Medical Congress conveys the following information, which is additional to that which has been published in the medical journals:

As it is too late to send tickets to the American Congressists, they are requested to send to the Secretary-General at Moscow, their addresses in London, or Berlin, or Vienna, or Paris, or to avail themselves of the National Committees in those cities, in order to receive their tickets and free passes over Russian railroads in those places.

The free passes are valid from July 13th to September 13th over the following routes:

Eydkunen to Moscow and back; Moscow to Petersburg, or Moscow to Graniza, or Moscow to Odessa, or vice versa; Graniza to Petersburg (or Odessa, or Eydkunen, or Ungheui, or Alexandrowo) or vice versa.

Different lines going and returning may be chosen, and stop-over is permitted.

Eydkunen to Petersburg is excluded from the free list.

A. JACOB, Chairman American National Committee.

SOCIETY NOTICE.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION. — The next meeting of the Mississippi Valley Medical Association will be held in Louisville on October 5, 6, 7 and 8, 1897.

DR. H. W. LOEB, Secretary, 3539 Olive Street, St. Louis.

BOOKS AND PAMPHLETS RECEIVED.

Local Anesthesia and Anesthetics. By E. J. Mellish, M.D. Reprint. 1897.

Who Discovered Anesthesia? By Joseph H. Hunt, M.D., of Brooklyn, N. Y. Reprint. 1897.

Strophanthus: A Clinical Study. By Reynold W. Wilcox, M.D., LL.D., New York. Reprint. 1897.

Address.

THE CENTENNIAL INTRODUCTORY ADDRESS, DARTMOUTH MEDICAL SCHOOL, JULY 14, 1896.

BY G. A. LELAND, M.D., BOSTON.

On the 117th page of the last general catalogue of Dartmouth College is the momentous announcement that the one hundredth annual address is to be delivered at this time and place. That this is the *one hundredth annual* occasion of this nature, of itself furnishes us with food for reflection and retrospection; and though it is not my purpose, even if I were able and you had patience to hear, to place before you the status of our art and science at that long-gone period and all that has happened since, yet it may not be unprofitable for us to look back to a few salient features of the century that is past, that you may infer how meagre and barren was medicine as then known in comparison with what it is to-day.

Now, gentlemen, the first students of this school were cotemporaries of a most remarkable physician of London, in whose life we may find many features the contemplation of which may be both profitable and interesting, not only because it is the life of one possessed of a wonderful intellect, a prodigy of learning, and because that prodigy lived up to the promise of his early years, but because it shows that the whole of the scientific knowledge of that time could be compassed by one human mind.

Dr. Thomas Young was born on the 13th of June, 1773; learned to read at two years; had read the "Book of Books" through twice at four, and began Latin two years later. At thirteen, it is related of him, that by selling stationery, etc., he collected five shillings which he added to the 10s. 6d. given him by his parents, and bought some Greek and Latin books and a Hebrew Bible, for which latter he gave one-third of his capital, namely, five shillings—not an end-of-the-nineteenth-century taste for a boy of thirteen years. Before he was seventeen, he had read the principal Latin and Greek authors, and many in French, and much in mathematics, natural philosophy, natural history, botany, etc.; and in the next three years the number of works in these subjects and in chemistry, medicine, history and literature which he devoured is almost incredible, especially as he is described as reading them in a studious and painstaking way, never hastily, but with a memory singularly tenacious, never forgetting what he had mastered. From all this it must be concluded that he was a recluse, taking most pleasure and comfort in segregation, pursuing his studies and investigations alone, with a strong, self-reliant mind.

The Rev. George Peacock, his biographer, says of him that he was "at an early period of his life an accurate classical scholar; perfectly familiar with the principal European languages; well acquainted with mathematics, and with almost every department of natural philosophy and natural history; profoundly versed in medical and anatomical knowledge; and in possession of more than ordinary personal and ornamental accomplishments."

And the same author says "that the principal causes of the extraordinary success of an education carried on for so many years with so little assistance

from extrinsic sources, were these"—and here we may all get an inspiration for the conduct of our own lives, whether we are just starting out, or howsoever far we have advanced on the road towards success—"the principal causes were these: the peculiar constitution of his own mind, his great industry, his conviction that what one man had accomplished another might accomplish also, the determination to master *every branch* of knowledge whose acquisition he thought necessary or desirable."

In 1752 (nineteen years of age), he began the systematic study of medicine in London, influenced in his choice, no doubt, by his uncle Dr. Brocklesby, a successful London practitioner. He then went to Edinburg, to Göttingen, and after travelling (mostly a-foot) over a large part of Germany, and becoming personally acquainted with the principal savants of the land, he returned to Cambridge (1797) to take up the legally required residence of six years before he could make his M.B., which he did in 1803, at thirty years of age. And after the requisite five years more, at thirty-five, he received the degree of M.D., in 1808. He began practice, however, in London early in 1800, three years before he received his first degree. In the world's metropolis, however, as is the case in most large cities, a physician must wait many years before he secures sufficient recognition for constant occupation. This, fortunately for the world, never came with Dr. Young; largely perhaps because of its ceaseless activity his mind required more to feed upon than ordinary minds.

In 1801, he accepted the professorship of natural philosophy in the Royal Institution. Who of us would assume the duties of so arduous a position after being one year in practice? In this position he did some of the most important work of his life—establishing the undulatory theory of light (which, however, had been merely mentioned something like a century before), elucidating the interference phenomena of light also; doing much in optics and in the anatomy of the eye, and it is curious to us now to read that he considered the substance of the crystalline lens to be muscular. But he held this professorship only two years, resigning because he did not wish the dear public to hold the opinion that he was anything but a physician, lest it interfere with his medical practice. Do we not here see a phase of medical human nature in a trait which is even in evidence at the present day—the anxious desire that the *οἱ πολλοί* shall think well of us?

In 1811, after an unsuccessful trial four years earlier, he was elected one of the physicians of St. George's Hospital, which position he held for the remainder of his life; and it is said of him, that his practice was very successful, that his treatment was much in advance of that of his colleagues.

In 1813 (forty years of age), appeared his first medical book, "Introduction to Medical Literature, including a System of Practical Nosology," a work of great labor, and of great assistance to students and investigators.

In 1815, appeared his last medical publication, "A Practical and Historical Essay on Consumptive Diseases."

After this, in addition to his medical practice, he turned his mind to perhaps more intellectual activities. He was one of the most learned exponents of Greek criticism of his time, able to use that beautiful language almost as his mother tongue; and his work in

the interpretation of Egyptian hieroglyphics is classic even to the present day.

What he did in further scientific investigations, in optical discoveries, in computation of longitude, in the value of life and life assurance, etc., is too far reaching to be mentioned at the present time; and I am afraid I have wearied you in what I have already cited in the life of this remarkable man, who died in May (10th.) 1829, at fifty-six, probably of valvular disease of the heart.

But, apart from the many features of his life which we may bring home to ourselves with profit, the point I wish to bring out is this, that the whole range of human knowledge at the time of the infancy of this medical college was compassed by one human mind, which also added very much thereto. Should any individual of us at the present day set out with a similar object in view, what a task would be laid before him! Setting aside as irrelevant to our purpose all the enormous advances which have been made in natural science, in chemistry, geology, astronomy, biology, in the new science of electricity (then in its infancy, whose birth shall ever be associated with the name of that great American, Benjamin Franklin), and in all the other sciences and arts which contribute to the sum of human living and human progress, and coming into the more restricted field of our own science and art of medicine and surgery, how stupendous would be the task of any one whose ambition would lead him to attempt to master it all! Those pioneers, the advance guard, the specialists, a great army of careful, painstaking, minute investigators, have pushed forward till the sum of what is known in *any one* of the special branches of medicine—such as ophthalmology, otology, laryngology (including rhinology) gynecology, neurology and dermatology—not to mention general medicine and general surgery, and what they have contributed to them, is enough for the employment of all the energies of one poor human mind at the present day. And it is probably not untrue that the mass of literature published in any one of the specialties mentioned is to-day greater than that of the whole of medical literature at the beginning of this century.

The handful of intrepid men who came away up here among these everlasting hills, away from the dust and the turmoil, the slums and the clinics of the larger cities, did it with the idea, more prevalent then throughout the country and the world than now, that the experience of others, as gained from their writings, supplemented by their own, was a sufficient basis for the propagation of a knowledge of the empirical science of medicine. And, gentlemen, it is a noteworthy fact that they were contemporaries of that great country practitioner (and it must be admitted that the majority of the students of most medical schools are to be extra-urban practitioners) who one hundred years and two months ago to-day (May 14, 1796) first inoculated a boy eight years of age, James Phipps, with vaccine matter taken from the hand of a dairymaid, Sarah Nelmes, who had become inoculated from one of her master's cows. This quiet, studious, painstaking man first had his attention drawn to the matter while yet a student twenty-five years previously, and had called the attention of his teacher, the great John Hunter, to it. But he, Hunter, seems not to have taken much note of the matter, and his reply to his pupil was, "Do not think, but try; be patient, be accurate." This was rather

equivocal advice; and after ignoring the first part of it and following the last part for twenty-five years, carefully collecting his facts and studying them in all their relations, Edward Jenner made a name for himself which shall ring down the ages as long as time and history shall obtain with the human race—Edward Jenner, the conquerer of one of the most virulent, loathsome and fatal of the ills which human flesh is heir to; a disease, the presence of which spreads terror and panic; and which at his time and before was so common that Sir Gilbert Blane told the House of Commons that at the end of the last century an adult who had not had small-pox was scarcely to be met with or heard of in the United Kingdom. So prevalent was this disease that various authorities estimated the annual death-rate in Europe from it alone to be 210,000 to 500,000. Bernoulli, the celebrated mathematician, believed that no fewer than fifteen millions of human beings were destroyed by small-pox every twenty-five years, that is, 600,000 annually. De la Condamine estimated that it destroyed, maimed or disfigured one-fourth part of mankind. And the *Medical Press* recently stated that fifty millions of people died in Europe of small-pox in the eighteenth century.¹ Macaulay, the historian, observed that the disease was always present, filling the churchyards with corpses, and leaving on those whose lives it spared the hideous traces of its virulence. "If a modern traveller," said one observer, "could be transported to London in the early part of the present century, no peculiarities of architecture, dress or behavior, would be so conspicuous as the enormous number of pock-marked faces he would encounter at every turn."²

Such being the condition in pre-vaccination times, what is it now in countries where vaccination is compulsory? In England, from an average death-rate of 2,000 (sometimes even amounting to 6,000 per million inhabitants), since compulsory vaccination (1871) during the ten years, 1885 to 1894, the death-rate has been only 26; and in Prussia, where vaccination is even more thoroughly carried out than in England, the rate has been only 7 per million yearly for a similar period. Whereas formerly Buchan, in his "Domestic Medicine" (fourteenth edition, 1794), says, "This disease is so well known that a minute description of it is unnecessary." Now, many of you will practise for years, perhaps throughout your whole professional career, and never see a case. It is only a few years ago that an English army surgeon in South Africa failed to recognize and isolate a case, and, an epidemic ensuing, was nearly mobbed for his carelessness.

What has wrought all this change? Simply the careful observation and the ability to draw practical conclusions of an English country practitioner a hundred years ago. And how significant is it that the great John Hunter who had the stupendous truth almost thrust upon him by his distinguished pupil should have failed to make that great name for himself and to earn the undying praise of a grateful world! And what were the emoluments earned by Edward Jenner himself? Grants of money by Parliament, medals, honors, diplomas, statues, etc., were heaped upon this modest man, who *sought not his own gain*, but freely and fully published his great discovery to the world.

This year of 1896 is again noteworthy, because October 16th is the fiftieth anniversary of the first

¹ Lancet, Jenner Centenary Number, May 23, 1896.

² Medical Record, October 5, 1895.

application of sulphuric ether in the Massachusetts General Hospital for the induction of general anesthesia, by Morton and Jackson; and that that was not so very long ago is evidenced by the fact that the man who probably made the ether then and there used is now living in Boston.³ And though there are several claimants for the honor of its first administration, it is evident that the world first knew of the great discovery from the work done with it in the New England metropolis. It was known before, to be sure. As early as 1795, Dr. Pearson used it for relief of spasmodic respiratory affections. That it would produce insensibility was shown as a laboratory experiment by Goodwin in 1822, Mitchell in 1832, Jackson in 1833, and Wood and Bache in 1834; but its first use as a surgical anesthetic was as mentioned above. The news of this remarkable performance reached England on the 17th of December, and on the 21st, Mr. Liston, the eminent surgeon made use of it.⁴

Now, gentlemen, I might dilate on the immense advantage of the glorious discovery of anesthesia, but this has been already frequently done by others.

"Is there anything in human history which more sternly teaches that man must win every boon of nature by his own ceaseless striving than that this simple chemical and physiological secret of anesthesia should have lurked so strangely long in its easy formulæ, undeciphered, through all those waiting generations when pain was an omnipresent tyrant whom science could not control, and the operating-room a torture-chamber, dreaded almost as much by the surgeon as by the sufferer?"

"Thus, in 1846, did the anesthetic age commence, giving to your art a sure control of anguish; to its boldest practice confidence, quiet and leisure; and to those who have to lie under that knife a sweet and complete oblivion. I [Sir E. Arnold] have myself known what it is to pass, fearless of the kind steel, into that world of black-velvet tranquillity of which your magic drug now keeps the gate, and to awake as good as healed, grateful beyond words for the soft spell of enchanted peace and the sure and faithful skill."

And what shall I say of the discovery of local anesthesia by cocaine by Dr. Karl Koller in or about 1886? It is second only in its valuable results to that of general anesthesia. Of what immense value is it in all operations and manipulations in the great field of the mucous membranes, in the eye, nose and throat! It has opened up the nose to us as it was never before shown, and it may be truly said that the whole science of rhinology had its birth in the discovery of the local anesthetic property of cocaine. Before this the nose was a veritable *terra incognita* till this agent banished the temporary swellings in the interior of that organ, and showed what was permanently obstructive; and then enabled us to accomplish its painless removal. Operations also within the throat, and especially those intra-laryngeal operations, among the most difficult and most delicate of surgery, are by it brought into almost

absolute control; and, moreover in the amount of comfort by it vouchsafed to sufferers from those incurable, painful affections of the throat, such as cancer and tuberculosis, it is one of the greatest boons brought to suffering humanity by our modern medical art. And the American people will ever owe a great debt of gratitude to it and to its discoverer because it so providentially came in season to mitigate the sufferings of the last days of that great heroic spirit, that idol of the nation, that great leader of her conquering armies, as he sat in his chair at Mt. MacGregor, fighting the only losing battle of his life; and it doubtless prolonged his life while with infinite patience he drove his pen to the accomplishment of his last great work (the writing of his "Memoirs"), which he so sadly undertook actuated by love of his family. How pathetic and significant his remark that even a swallow of cold water burned like liquid fire; and what a boon was the anesthetic power of cocaine!

Thus rhinology may be said to have had its origin in the discovery of cocaine, and from the better knowledge of the functions of the nose have resulted some of the greatest advances in the treatment of affections of the throat and ear; and, now, many minor and some major operations are being done under its use by a recently promulgated method of intradermic injection.

And, now, gentlemen, I have touched upon but two of the notable things which have occurred since the founding of this Medical School. The time is too short to speak of the great work of Sir Joseph Lister whose name will ever be associated with the antiseptic treatment of wounds. By his wonderful teaching of the germ theory and invention of sterilization, suppuration is brought under control and hospital gangrene, once the *bête noir* of hospital practice, is now only an historical curiosity. I take some satisfaction in having once seen a single case, but I find that most of my colleagues and medical friends have never had that opportunity.

Following on after Listerism, the perfected microscope showed the basis of the germ theory; and here the names of Klein and Koch are immortal; and from that great, new science of bacteriology has been evolved the antitoxins. Think of the enormous boon to humanity given us by Roux and Behring, by which that dread disease diphtheria, hitherto almost unconquerable, has in the last three or four years received such a staggering blow. From a death-rate of 40 to 60 per cent., according to the virulence of the epidemic, by the use of antitoxin the rate has been reduced to 12 per cent. in France, and to 11 per cent. in our Boston City Hospital. It has been estimated that by this new treatment 60,000 lives are saved annually in Europe.

And this, my hearers, could not have been brought about without the use of animals. The whole science of bacteriology, and much of that of physiology, depends on the study and observation of the behavior of living entities under given conditions. And whither shall we look for those entities, except to controllable animal life? A bill has lately been before the Massachusetts Legislature, whose object it was to obstruct and abolish vivisection; as Dr. Bowditch said, "it was utterly mischievous and would carry scientific medicine back to medievalism."

I bring this to your attention to enlist your influence against these antivivisectionists, these modern

³ Under date of December 16, 1896, Dr. C. J. Blake, of Boston, writes me as follows: "Fifty years ago my father, Mr. John H. Blake, conducting a series of experiments in the production of sulphuric ether, succeeded in obtaining a very pure article which he gave to his friend, Dr. Charles T. Jackson, for experimental purposes; and it is presumably this ether which was given by Jackson to Morton. At this time Mr. Blake was also manufacturing purified ether on a commercial scale."

⁴ Chambers Encyclopedia, and Encyclopædia Britannica.

fauvities (probably mostly childless) who would set the value of the lives of the dear little children, the sunshine of the home, below that of the insignificant guinea-pig, in which the Klebs-Löffler bacillus can best be studied, or below that of the cheap dray-horse which is more valuable as a furnisher of the life-giving serum than he could be in any other capacity.

Now, gentlemen, I am well aware of the fact that I have not done what might have been expected of me; that is, to give you a review of the branches of medicine embraced in my own department. I have not told you of the great progress which has taken place in otology, where practice has made such marked advances that the times of simple syringing, of placing almost every known substance into the aching ear, or of doing what is almost but not quite so bad, leaving the diseased ear alone to take care of itself, are giving place to those of an active, rational treatment which is calculated to preserve the hearing of a very large portion of mankind whose ears in times comparatively recent were lost by neglect and meddlesome interference. I have not told you how many obscure cerebral diseases of the earlier part of this century — yes, even to within a short decade — are now classed under the head of "otitic brain disease" because it has been found that their origin is in inflammatory invasions of and from the middle ear. I have not taken up the subject of obstructive growths in the nose and nasopharynx, which latter, principally under the name of adenoid vegetations (which name is now so familiar even to the laity) were only discovered and published to the world so recently as 1868 or 1870, by the late Dr. Wilhelm Meyer of Copenhagen; which growths have been found to be the cause of so much of the earache of childhood, thus leading on to the deafness of middle age. I have not gone into the wonderful history of throat diseases brought about since the invention of the laryngoscope by Manuel Garcia in 1864, which has opened up to us many of the obscure causes of cough and of obstructed respiration. I say I have not gone into all these points in my specialty, because I thought you would hear enough of them later; and then it is so alluring to get out of the deep ruts in which I am always travelling, and to look abroad into the attractive fields of other research that I have indulged my own desire and so led you with me on an excursion which to me has been very pleasant, and I hope not without some degree of pleasure and profit to yourselves.

Now, I cannot conclude without expressing to you a very deep sense of personal bereavement in the great loss which this Medical School, this college, this community, the medical profession of this State and of New England, has sustained in the recent death of the Dean of this Medical Faculty. As I come up here this year, I miss his genial smile, his cordial greeting, the sense that there is a guiding genius at the helm who is ever present, handling with a fatherly, masterful detail everything which pertains to the institution. In his daily life, too, we may find much to emulate with profit, for it was his principle to do everything well, to do with his might whatsoever his hand found to do, a man of firmness of character, of sterling worth and conspicuous honesty and honor. There was no shirking in the nature of Dean Frost, but it was his nature to put the whole of himself into his life work; and so we have found it in the history of this Medical School, to which he gave his best ener-

gies without stint — this Medical School which owes so much of its present excellence and high standing to his thoughtful and forceful management.

And, finally, gentlemen, there are a few personal words which I would inflict upon your hearing. You have chosen a calling which is most fascinating but which is arduous, which will claim every moment of your time if you follow it faithfully from now till you lay aside forever the implements of your toil. There is a glamor about it in the minds of the laity when they see the physician come to look at the tongue, to feel of the pulse, perhaps take the temperature, and examine some organ — and pocket his apparently easily-gotten fee; but the long nights of ceaseless labor, the burning of the midnight oil, the long and expensive years of study in preparation, enter not into the ken of those who are so easy with adverse criticism, but so grudgingly slow with adequate reward. The position of a physician at the present day is far better than it was when Hogarth and Molière ridiculed the calling of this most sacred profession, when, perhaps, then as now there were some who deserved ridicule; but to him who enters upon it with soberness, with a single eye and a steadfast purpose, there is nothing in it but that which should command his most noble efforts and so merit the highest praise. As one quoted before (Sir Edwin Arnold) so beautifully puts it: "And the nobly educated man who knows himself the accepted servant of science and nature, and the messenger, as far as may be, of Heaven's eternal pity, has moments, we all believe, of rich success and boundless recognition, that makes his fees the very smallest part of his after-payment in life."

It is not only a life-work of toil, but one of danger, for the pestilence which slayeth at noon-day is to be your constant companion. At every turn we meet hordes of invisible enemies which the microscope has only recently revealed to us, but whose deadly strength is too abundantly proven by the long list of medical men who have succumbed to disease contracted from their patients. Therefore, I say that this medical life which you have chosen with a bravery which you do not now appreciate nor comprehend, is no sinecure; but to the strong belongs the victory — the strong in body, the strong in mind, the strong in heart and the strong in faith.

PERICARDITIS: SOME POINTS IN ITS DIAGNOSIS AND TREATMENT.¹

BY FREDERICK C. SHATTUCK, M.D.,
Professor of Clinical Medicine in Harvard University.

THERE is perhaps no disease with which we are so well acquainted more frequently overlooked during life than pericarditis. Among the reasons for this failure in diagnosis may be mentioned, first, the fact that pericarditis, like the inflammation of the other serous membranes, is commonly and perhaps invariably secondary. Rheumatism is the most frequent primary disease; but in rheumatism the endocardium is attacked even more frequently than the pericardium, and thus two possibilities of error are afforded. In the first place, it is in some cases not easy, unless after repeated careful examination, to determine posi-

¹ Read at the Twelfth Annual Meeting of the Association of American Physicians, Washington, D. C., May 5, 1897.

tively the endo- or exo-cardial origin of adventitious sounds; and, in the second place, both membranes may be simultaneously attacked, while the auscultatory sounds of the endocarditis wholly or very largely mask those of the pericarditis. Again, it is notorious that, especially in children, the rheumatic poison may be manifested so slightly in the joints that it is not thought worth while to call in the doctor, who thus misses a chance of noting the commencement of an inflammation resulting later in adherent pericardium or a damaged valve. While many other joint-diseases and infections may be complicated by pericarditis, in none, save pneumonia, is it so common as to lead us to be specially on the watch for it. Tuberculosis may attack the pericardium either alone, just as it may attack the pleura; or together with other serous membranes, as well as parenchymatous organs in varying degree, as in the acute miliary form; or, third, as an extension from the contiguous lung or pleura in chronic pulmonary consumption. Such extension seems to be rare, considering the very large number of cases of fatal phthisis. Except in cases where the tuberculosis is confined to the pericardium, and is then accompanied by considerable effusion or more or less pronounced local symptoms, the condition of the serous sac is liable to be overlooked. In pneumonia and other forms of lung inflammation, and also in pleurisy complicated by pericarditis, it may easily be impossible even for the most skilled and careful observer, owing to the anatomical relations of the organs, to detect and differentiate the pericardial inflammation.

The frequent association of pneumonia and pericarditis, as well as the latency of the latter, has forced itself upon my attention of late. Of 57 cases of pneumonia under my care in the hospital during the past three years 20 have come to autopsy. In 13 of these pericarditis was found. In 5 of the 13 pericarditis was detected during life. In the other 8 it was carefully sought for, and the absence of its signs was recorded. In 7 of the 13 cases the pneumonia was right-, in 6 left-sided. This experience differs widely from that of Osler, who found pericarditis in only 5 of 100 autopsies of those dying from pneumonia in the Montreal General Hospital.

In a similar way hydropericardium, with or without inflammation of the sac, in cases of nephritis and cardiac insufficiency may be quite masked by hydrothorax, ascites, passive congestion of the liver and other results of hydemia and stasis.

Symptoms, again, are not to be relied upon as suggestive of pericarditis or in any way distinctively diagnostic. The primary disease may be so severe as to render the additional load almost imperceptible to the observer. Pain in the cardiac area is very frequently absent, often slight, most apt to be marked in the relatively vigorous with mild primary disease. It is, perhaps, a fair general statement that the less severe the original disease the more likely are symptoms suggestive of secondary pericarditis to be present. Ordinarily there is nothing about the facies, position, breathing or pulse essentially different from what may be seen in many other forms of intrathoracic disease. The temperature-range, as in other serous sac inflammations, has no distinctive peculiarities.

Diagnosis must, then, rest mainly on physical signs, but these may be entirely absent. I have deeply stamped in my memory the case of a physician's wife, some years ago. Double dry pleurisy was present,

and, believing that pericarditis must be also present, twice daily for nearly two weeks I examined the precordia with the greatest care without ever succeeding in detecting any friction which I could refer to the pericardium. At the autopsy the pericardial surfaces were uniformly united by delicate and recent adhesions. Friction, again, is proverbially often evanescent and may come and go between examinations which may be separated by too long an interval, the first having given negative results, and no local or circulatory symptom arising. It has happened to me more than once, the last time within a few months, to order a patient with well-marked pericardial friction sent to my clinic at the amphitheatre the next morning, that students might have the opportunity of listening to it, and then to find that the friction had disappeared entirely. Another trap which is set for us is the pleuro-pericardial friction. If there is no other evidence of a process in the lung with which pleurisy is apt to be associated, and no other evidence of pleurisy than friction within the precordial limits, the chances are in favor of the pericardial origin of the friction, especially in the rheumatic cases. Conversely, with other evidences of pleurisy or of a cause for it, a friction in the above area is probably pleural; but we have all encountered cases where a double friction accompanying the cardiac movements and persisting during cessation of respiration has subsequently proved to have originated solely in the pleura bordering on the heart.

Another pitfall is, the lungs and pleura being beyond suspicion, the association of endo- and pericarditis of undoubted rheumatic origin, if you like. Two recent personal cases illustrate this point:

CASE I. A boy of six was seen with Drs. Miles and Coggeshall, acutely and very seriously ill with symptoms of defective circulation; endocarditis was apparently unquestionable. During both the consultation and subsequent discussion of the case the possibility of considerable pericardial effusion occupied the foremost place. The enlargement of the area of cardiac dulness was quite moderate; gentle percussion was resonant in the fifth right interspace (Rotch); the dulness did not seem to extend to the left beyond the impulse; the precordia was not prominent, and I believed that an attempt to tap the pericardium would pierce the ventricle, and thereby hasten death. The end came in about twenty-four hours. There was no autopsy, but the undertaker states that from the incision which he made near the heart for embalming purposes nearly a quart of clear, yellow fluid escaped. My inevitable conclusion from this is that death was immediately due to a large pericardial effusion, the removal of which might have saved the child's life; but which had not manifested its presence by signs characteristic of such condition, though the possibility of its presence was carefully weighed.

CASE II. A few weeks later a boy of eleven was admitted to my ward with a doubtful history of mild articular inflammation, a systolic apex souffle, and a double murmur below the base on the left so soft and regular as to suggest an endocardial origin, though pressure with the stethoscope increased its intensity. A few days later the double murmur changed its character, and I was satisfied that it was due to pericarditis (Case VIII); in short, we had a rheumatic endo-pericarditis. Soon after, the pulse rose to 160 and was paradoxical; orthopnea and precordial pain were present, and the urine fell in quantity. Coincidentally the area of dulness increased and extended to the left of the impulse. I pushed a good-sized trocar and canula into the fifth space an inch beyond the nipple just inside the line of flatness. That I entered the pericardium was proved by getting about two drachms of serous fluid. The end of the canula moved freely, as if in a cavity; adhesions were not

felt breaking; perviousness of the canula was proved by reinsection of the trocar. The cardiac movements communicated to the canula were alike visible and palpable, but no more fluid could I get. From this time the boy began to improve, morphia and alcohol being continued, and a week later all signs of pericarditis had disappeared. Here I was either mistaken as to the amount of effusion or it was trabeculated something like a varicose vesicle. The latter possibility was suggested to me by a previous case (Case I) in which I could not extract as much fluid as the signs would warrant me in expecting to get, though I tapped in several places.

These cases show that I, at least, find it sometimes difficult, though trying to exercise due diligence, to determine the presence or degree of pericardial effusion, especially when eudocarditis is also present, though the lungs and pleuræ are clear.

Dry pericarditis is not to be diagnosticated with certainty in the absence of friction, the possible pleural origin of which is always to be borne in mind. Practically, perhaps, it is not of much consequence, as obliteration of the sac is the worst sequence.

A small effusion may be suspected, but is not to be made out with certainty. What the least amount of fluid that can be detected may be, I cannot state. I suspect that it is not fixed, but varies with different patients as well as with different observers. The practically important thing is to be able to recognize a considerable or large effusion, to decide rightly whether tapping is necessary and to practise it successfully. Since I published a little book on "Auscultation and Percussion"² I have had more experience with pericardial effusion than in all the rest of my professional life, and my belief as to the shape of the dulness produced by effusion differs now from that of most writers on the subject whose views I then accepted. I do not find, namely, that the dulness of the large effusion is either pear-shaped or pyramidal. To my percussion the area of dulness is simply that of the normal heart equally extended in all directions; therefore, of course, it is also that of a symmetrically enlarged heart, though the latter can seldom if ever produce so large a dull area. It is always my attempt in cardiac percussion to map out the limits of the heart itself, disregarding the smaller area, that of cardiac flatness so-called, within which the pericardium comes immediately in contact with the chest-wall, uncovered by lung. By inserting needles along the line of dulness as determined during life or just before the autopsy in a number of cases, and then opening the body, I have satisfied myself that substantial accuracy is thus possible. The pyramidal and pyriform-shaped areas may result from aiming to mark out flatness rather than dulness, a procedure which the very gentle percussion required in this work renders more difficult to me than the plan which I have pursued. In several cases of large effusion I have noticed dulness below the left clavicle as compared with the other side, but have never been able to make out any percussion changes in the back which I could connect with a distended condition of the pericardial sac. The impulse of the heart may or may not be visible, palpable, or both. In the cases in which it is accessible to sight or touch distinct extension of the dulness to the left of such impulse has seemed to me a very important physical sign of effusion within the sac. If no impulse can be seen or felt the maximum intensity of the first sound must serve as the best indication of the

seat of the apex. Change in the percussion-sounds, upward or laterally, with change in the position of the patient, is very valuable if it can be distinctly made out. Such change was noted in three out of four of my recent cases. Silence on this point in the others tends to show that the sign was not specially studied. Prominence of the precordia is, I am sure, not frequent, and no important conclusions should be based on its absence, which I have noted even in a young subject. The lungs offer less resistance than the chest-wall and may both retract away from the distended pericardium. Moreover, the limits of possible effusion are more definite in the case of the pericardium than in the case of the pleura. Paradoxical pulse was noted in five out of eight cases. Effusion was large or considerable in all where it was present; but the value of this sign is lessened by the fact that it may be found also in other conditions, though, perhaps, less constantly. Repeated and sudden collapse was noted in six cases, and therefore seems to be a sign worth mention. In none of my cases were aphonia, dysphagia or irritative cough noteworthy symptoms.

The diagnosis of uncomplicated, considerable pericardial effusion should ordinarily present no great difficulty, especially if the observer has had the opportunity of watching the case and noting the development of the symptoms and physical signs. A weak and dilated heart, an encapsulated pleural effusion, and possibly a mediastinal new-growth are the conditions involving most liability to error. The difficulties of diagnosis in complicated cases have been already dwelt upon sufficiently in a communication which makes no pretence of exhausting the subject, but is rather a record of personal experience.

Treatment.—In a general way I must confess my scepticism as to the value of therapeutic measures other than rest as materially modifying the formation or promoting the absorption of pericardial effusion. I have seen effusion increase in spite of remedies, and I have seen it rapidly diminish without remedies. Morphine should be used freely if pain demands it. Alcohol and digitalis should be given if the state of the circulation seems to call for them. Blisters I never use, as my faith in their efficacy is small, and I know they interfere with close study of the case, and may interfere with necessary puncture. The ice-bag I have applied when it was grateful to the patient. I relate annually to my students a story of Sir William Gull, told me by Dr. Pye-Smith. At a consultation Gull detected a pericarditis which had been overlooked by the attending physician, who was perhaps unduly apologetic for his oversight. After hearing him out Sir William remarked: "Oh, it is all right. Perhaps it is just as well you did not find it, for if you had you might have treated it." It is my belief that he meant to enounce a general principle rather than to express doubts as to the skill or wisdom of the individual. To tap or not to tap, that is the practical question to my mind; and unless we are quite sure of our diagnosis of a large effusion the question may be a very nice one. Whatever may be our attitude to-morrow, to-day we cannot regard puncture of the heart as an innocent procedure, and we cannot bring ourselves to interfere with the pericardial as freely as with the pleural cavity. The consequences of an error are liable to be too serious according to our present knowledge; and yet the fact that I have in seven cases attempted to tap the pericardium, in six successfully, is

² G. S. Davis, 1899.

proof, I think, that I am not more timid in this respect than most people. I believe I have saved at least two lives by tapping. In Case II the fluid finally ceased to reaccumulate. In Case VII tapping proved the necessity for free incision. I have never regretted having tapped. I have reproached myself for not having tapped.

There is a double danger in every large pericardial effusion; that of sudden and that of gradual failure of the heart, embarrassed as it is. The frequency of sudden collapse in my cases has been already alluded to. Fortunately in none was it fatal; but the withdrawal of a relatively small amount of fluid may obviate this tendency. Moreover, it has seemed to me, alike in pericardial and in pleural effusion, that absorption sometimes follows the removal of even a small amount so rapidly as to suggest a causal connection. Of course, absolute proof of this is hard to obtain, and perhaps I should exercise fully as much scepticism here as with regard to drugs, blisters, and the like. No hard-and-fast rule can be laid down with reference to when to tap. Each case must be determined on its merits; but if the diagnosis of considerable effusion seems sure, if the breathing and circulation show danger signs, and if the patient be not under close supervision of a competent assistant, I believe it is safer to puncture. If the case is uncomplicated or largely so—that is to say, if it be only the effusion which seems to threaten life—interference is more strongly indicated than if the effusion be merely a single factor, as in Case IV, where malignant endocarditis was strongly suspected. If interference is decided upon, of course, cleanliness of hands, skin, and instrument must be ensured. Personally, I prefer a moderate-sized trocar and canula, attached to the aspirator with a side switch.

A smooth canula can be moved freely in all directions within the sac if adhesions or other cause impede the flow, and one feels no nervousness in coming in contact with the moving heart. Repeatedly I have felt the motions with the utmost distinctness, and have indeed sought them when the results were scanty.

The Point of Election. The points advised as most suitable for puncture by most writers group themselves in the superficial cardiac space, the small triangular area where the pericardium is not covered by lung; that is, the fourth and fifth left interspace, either at the sternal border or an inch from it, are mentioned by all authorities. Rotch has suggested the fifth right interspace at the sternal border, basing on his cocaine-injections in the cadaver the opinion that the dilated heart never extends into this space, and that puncture there is consequently safe. The left costo-xiphoid angle, the instrument being thrust upward and somewhat backward, is also recommended for safety. Here I have punctured once only, and then after death, Case IV. The ease with which I withdrew a pint of fluid inclines me to try this point again, and during life, if occasion offers. This inclination is strengthened by preceding several autopsies recently by puncture in this spot. The liver or peritoneum may be wounded in reaching the normal pericardium at this point; but this danger must be small when the pericardium is distended with fluid.

The fact that the line of dulness extends to the left of the impulse—for the probable reason that the fluid seeks the lower and lateral portions of the sac, which, moreover, are more distensible—first led me to try

tapping just inside the outer left limit of the line of dulness, and it is here that I have made my most productive punctures, withdrawing once thirty-six ounces; again in the same case (II) twenty-four and sixteen ounces; and in another case (VII) sixteen ounces. I must confess I feel less nervous about thrusting a sharp instrument in so far to the left than directly over the heart. The lung ought to be wounded by puncture so far to the left. This has not seemed to occur in any of my cases, though in Case VII the incision was made to the left of the nipple and opened the left pleural cavity, producing pneumothorax and probably causing the subsequent empyema. My colleague, Dr. Cutler, agreed with me in the opinion, which was later shown to have been erroneous, that the pleura was probably adherent at this point. This belief and the fact that I had already reached the fluid here, led us to advise it as the point of incision. The case has been reported in full, with critical remarks by Dr. Porter, who has since made many careful dissections which show that the fifth left interspace at the sternal border is the point of election for incision. This case is, I believe, the only one which has ever been treated by incision in the Massachusetts General Hospital.

Twice I have punctured in the fourth right space near the sternum, without getting fluid in either case. In one of these cases puncture in the fifth left was productive, in the other it also was dry. Very recently my colleague, Dr. Vickery, drew three and one-half ounces from the pericardium through the fourth right space. The patient who had also pneumonia, died that night, and the autopsy showed about a pint of fluid still in the pericardium.

The following table shows the seat and result of my punctures.

Fourth left	once	fluid.
Fifth left	eight times	fluid twice.
Sixth left	three times	fluid twice.
Fourth right	twice	no fluid.
Left costo-xiphoid angle	once, post-mortem	fluid.

CASE I. Female, aged twenty-four years, single; entered the hospital January 19, 1891, with acute polyarticular rheumatism.

January 23d. Pericardial friction; rising temperature and pulse.

January 28th. Chest as in diagram. (Fig. 1.)

Tapped in fifth left interspace, three inches from median line. One ounce of bloody serum obtained; heart felt on canula.

Tapped again in fourth right space, two and one-half inches from median line; dry tap.

January 31st. Paradoxical pulse. Tapped in fifth left space, four and one-half inches from median line; half an ounce of bloody serum. Next day tapped in same space six and one-quarter inches from the median line; dry tap.

April 12th. Discharged well.

CASE II. Male, colored, aged forty-seven years; entered the hospital on October 26, 1892. Had suffered from weakness and dyspnea for eight weeks, but had worked in a damp place until entrance. Examination showed pericardial friction with muffled sounds at the apex.

November 19th. Steadily losing flesh and strength, but without special symptoms till to-day, when sudden, gasping respiration, weak and almost imperceptible pulse, and fainting. Area of dulness as in diagram. (Fig. 2.)

Tapped in fifth left space, one inch outside of nipple, removing twenty-four ounces of serous fluid, containing tubercle bacilli and also the "bacillus pyocyaneus pericarditis," described by Ernst in the *Transactions* of this

Association, 1893, p. 135. Great relief; heart felt on canula.

November 26th. Tapped for same symptoms as before; one pint.

December 17. Tapped for same symptoms as before; thirty-six ounces.

Both these taps were in the same place as the first.

March 5, 1893. Tapped in the sixth left space, one and

FIG. 1.

one-half inches beyond the nipple; one pint; paradoxical pulse.

March 12th. Eloped from the hospital and could not be traced.

CASE III. Female, aged twenty-four years; entered the hospital January 4, 1893, with precordial and poly-articular pains, orthopnea, and gasping, painful respira-

FIG. 2.

tion. Dulness beneath left clavicle, and cardiac dulness as in diagram. (Fig. 3.)

The same day, on account of sudden cyanosis and weak and rapid pulse (160), tapped in fourth right and fifth left spaces; both dry; heart felt on canula.

January 7th. Died; no autopsy.

CASE IV. Male, aged about seventeen years; entered on January 5, 1894, after six weeks of polyarticular rheu-

matism and cardiac symptoms for three weeks. A harsh, systolic murmur over the whole cardiac area.

February 8th. Pericardial friction.

February 17th. Dulness as in diagram. (Fig. 4.)

Sudden cyanosis and collapse. Tapped in sixth left space, one and one-half inches outside the left nipple, and two ounces of bloody serum obtained.

February 19th. Died. No autopsy was permitted, but

FIG. 3.

I tapped after death at the left costo-xiphoid angle, obtaining a pint of serum.

Whether in this case the puncture during life was too far to the left, or whether the effusion increased between that time and death, we have no certain means of knowing. The former seems more probable.

CASE V. Male, aged six years; entered February 17,

FIG. 4.

1894, with a history of fever, weakness, dyspnea, and pain in the chest for ten days. Leucocytes, 18,000.

February 19th. Pericardial friction.

February 21st. Dulness as in diagram, shifting with change of position. (Fig. 5.)

February 26th. Sudden cyanosis and collapse. Tapped in fifth left space, near sternum; one ounce of serum. Died the same day; no autopsy.

CASE VI. Male, aged forty-seven years; entered April 2, 1895, suffering for four days with pain in various parts of the chest, depending somewhat on position. Cyanosis, labored breathing. Friction apparently pleural, over fourth and fifth left costal cartilages; no distinctly pericardial friction. Paradoxical pulse; delirium.

April 5th. Area of cardiac dullness has steadily increased, and is now as in diagram. (Fig. 6.)

FIG. 6.

Died the same night. Autopsy: A pint and a half of sero-fibrinous fluid in the pericardium and one pint in the right pleural cavity.

In this case the pericardium ought to have been tapped, perhaps saving life.

CASE VII.³—E. C., my junior interne in the hospital, aged twenty-six years, was taken acutely ill October 23, 1895, with pneumonia of the right lower lobe.

FIG. 6.

October 28th. Dry pericarditis. Effusion soon followed, seemed to diminish, but returned and increased.

November 22d. The pneumonia having cleared, the condition was critical, the pulse paradoxical, the precordial dullness as in diagram. (Fig. 7.)

After consultation with Dr. Cutler, tapped in fifth left

space, one and one-half inches outside of the left nipple, removing a pint of sero-purulent fluid, containing pneumococci in pure culture. Marked relief.

November 24th. The fluid was evidently larger in amount than ever, and the pericardium was incised under ether by Dr. Porter, the cut being made just within the point of puncture. An amount of fluid, estimated at a quart, escaped; the left pleura was opened; improvement

FIG. 7.

in the pulse and loss of the paradoxical character was almost instantaneous.

December 4th and 24th. About six ounces of somewhat turbid fluid were taken from the left pleura. Cheyne-Stokes respiration was present for days.

January 23, 1896. Incision for left empyema (pneumococcus), with escape of a quart.

FIG. 8.

February 7th. Erysipelas of the whole back, neck and shoulders.

March 10th. Pus was let out of the old pericardial scar and of glands in the left axilla. Pneumococci.

April 27th. Discharged from hospital. Recovery of strength has been steady, though gradual. He is now in Europe, and is looking forward to resuming his studies in the autumn.

³ For full report of this case, see Boston Medical and Surgical Journal, May 6, 1897, p. 439.

CASE VIII. Male, aged eleven years; entered March 1, 1897, with subacute rheumatism, mitral regurgitation, and a pericardial friction.

March 5th. Pulse weak and rapid; precordial pain and dyspnea; paradoxical pulse. Tapped in fourth left space, just outside the nipple, and two drachms of serous fluid withdrawn. Dulness as in diagram. (Fig. 8.)

March 24th. Area of dulness much smaller. Symptoms abating.

April 1st. Discharged well.

REMARKS ON SYMPHYSEOTOMY.

BY GEORGE J. ENGELMANN, M.D.

THIS operation is one which merits our consideration, more especially so as there are those who are inclined to view askance, if not to ignore, the procedure as one of the many fleeting innovations of this progressive era, or as too crude or unsurgical as compared with Cesarean section, which is now extended, by reason of its success as a hospital operation in elective cases, upon most elastic indications to the minor degrees of pelvic contraction, and even into the realms of version and the forceps, with but little thought of symphyseotomy or premature labor.

This is not a new operation, as it has been known for over a century, and practised even in those early days with fair success and with excellent results as compared with Cesarean section; yet it has not received the consideration it merits until within the past decade; in that time it has undergone a crucial test, and must now be recognized as one of the accepted procedures of modern obstetric art.

Symphyseotomy holds an unquestioned place in operative midwifery; but its indications are yet to be fixed, its application and limitation to be defined. In the main, we may say that the operation pertains to the intermediate degree of pelvic contraction, that it replaces craniotomy on the living child and premature labor in the earlier months, and must be compared with Cesarean section on the one hand and high forceps and version on the other, the latter coming in contact with symphyseotomy in the minor contractions, and the former by its relative indications being almost a parallel operation. The indication for pubic section, as I would formulate it, is to be found in the slighter disproportion, two centimetres or less between biparietal and pelvic conjugate, because two centimetres can always be gained by the operation, or, in other words, with the average fetal head of this country, in a pelvis of between 7 and 9 cm. ($2\frac{1}{4}$ to $3\frac{1}{2}$ in.). As yet the various operators differ somewhat as to the sphere of the operation, at least in so far as its limits are marked by pelvic measurements alone, always an uncertain guide.

Pinard gives the widest scope to symphyseotomy, from a conjugate of 8 cm. ($3\frac{1}{6}$ in.), above which he resorts to premature labor, to one of 5 cm. ($1\frac{1}{4}$ in.), within the absolute indications of Cesarean section, thus confining Cesarean section to a pelvis of less than 5 cm. ($1\frac{1}{4}$ in.).

Leopold allows a much smaller range to the operation, but likewise applies it to the higher degrees of contraction, to those with a conjugate of 7.5 cm. to 6 cm., the limit for absolute Cesarean section.

Morissani himself does not carry symphyseotomy quite so far, limiting its application to a conjugate be-

tween 8.8 cm. and 6.7 cm. ($3\frac{5}{16}$ to $2\frac{1}{8}$ inches), very much the class of cases formerly consigned to craniotomy on the living child, and, if elective, to premature labor in the earlier months.

Tarnier gives preference to symphyseotomy in pelves of less than 8 cm., though he reports a series of cases of induced labor in contractions to 6.6 cm. ($2\frac{1}{2}$ in.), unfavorable by reason of the high fetal mortality. Leopold limits premature labor to a conjugate between 8 cm. and 7 cm., cases in which at term he advocates forceps or version in the flat pelvis and version in the justo-minor above 7.5 cm., symphyseotomy below. Tarnier gives preference to premature labor as the method of choice in pelves above 8.6 cm., when it can be inaugurated at the beginning of the ninth month.

Such have been the varied degrees of pelvic contraction to which symphyseotomy has been applied; and though the conditions and circumstances of the individual case will determine our choice of method, we must be guided to some extent by the results of the various operations resorted to in those intermediate forms of pelvic contraction for which symphyseotomy is advocated, and it is well to bear in mind that in these cases the mortality from forceps, version and premature labor is not a low one, but greater, I should say, than from the pubic operation.

The high-forceps operation is reported by Zweifel with a mortality of 7.3 per cent. The Dresden clinic from 1889-1894 records a maternal mortality of 5.17 per cent., and a fetal mortality of 21 per cent., 5.6 per cent. due directly to the operation; this is with a conjugate down to 7.5 cm. Version in this class of cases, to a conjugate of 7 cm. in the flat and to 7.5 cm. in the justo-minor pelvis, gives a mortality of 10 per cent. (Leopold).

Premature labor is practically without danger to the mother (perhaps one per cent.) when the operation is performed, as it usually is, by an experienced obstetrician; but the fetal mortality is great (40 per cent. in the cases reported by Tarnier, with a conjugate between 6.6 cm. and 8.8 cm.); and of these children born before the ninth month few survive the first year unless well cared for and favorably situated.

Craniotomy gives a mortality of perhaps 5 per cent.; Cesarean section 14 to 20 per cent.; and symphyseotomy, at the utmost, not over 11 per cent.—we may say, from 2 to 11 per cent.

The safety or danger of an operation is a patent argument for or against; and since symphyseotomy and the relative Cesarean section, as now advocated, apply to the same moderate disproportion between fetal head and maternal pelvis, to a similar class of cases, it may be well to note the relative mortality of these operations more carefully.

MORTALITY OF SYMPHYSEOTOMY.

	Maternal.	Fetal.

MORTALITY OF CÆSAREAN SECTION.

	Maternal.	Fetal.
In Vienna Hospital first 100 years	100%	..
In Paris during first 80 years	100	..
In Europe to 1868	46	..
In America to 1868	60	..
In America 1875-1885 (Harris), 33 cases	74	54%
In America 1882-1885 (Harris), 10 cases	90	80
In 1894, 44 cases in United States, Harris	27.5	..
In 1894, 40 cases in United States, Haven	22.5	..
Expunged,	9.0	..
Leopold	15 to 20	..
Singer	14	..

The lowest mortality of Cæsarean section is 14 per cent.; and that by only one operator, Sänger, in a small series of cases about equal in number to the symphyseotomies reported by Zweifel without a single death; even the mortality of the 303 cases collected by Harris, a total from all countries in 1895, is only 11 per cent.

Such are the results, as they have been obtained in cases taken as they come, one and all, not selected, none expunged, very much more favorable for mother and child than similarly collected Cæsarean sections and more favorable even than small series by expert operators; whilst those facts have but a very relative value, we cannot entirely ignore them.

The operation is decidedly less dangerous than Cæsarean section, and at least equally safe and more certain than forceps or version in the shorter sacro-pubic diameters. It is hardly more serious than premature labor in a pelvis from 7 cm. to 8.5 cm., and far more promising for the child.

Yet we are loth to adopt symphyseotomy, especially as compared to the relative Cæsarean section: it is not so brilliant and impressive an operation and does not appeal to the surgeon of to-day as so strictly surgical. But we must accept that procedure which promises the greatest benefit to our patient with least danger to herself and child. Then we must consider, not alone the great centres, the hospitals, but the country at large; and pubic section is of far more general usefulness, as it is not confined to such an extent as the Cæsarean to the surgical teacher or to the hospital and its trained staff. In fact, the first successful operation in this country, followed by others at a later day, was performed by a young practitioner in Texas.²

Symphyseotomy is eminently adapted to the more trying conditions met with in everyday practice, successful especially as an operation of necessity after forceps have been tried and have failed, when Cæsarean section is very unpromising. Whatever experience may henceforth teach or our preference dictate, with *moderate disproportion between head and pelvis*, not over 2 cm. with pelvic contraction not below 7 cm. (2¾ inches), pubic section is to be considered and is our only resource after an unsuccessful trial of forceps if the child is to be saved, replacing the brutal craniotomy of former days; and for the present we must accept such failure of forceps with moderate disproportion of head and pelvis as an absolute indication for symphyseotomy, for which we should always be prepared in the lesser degrees of pelvic contraction.

A REUTER'S telegram from Cape Town, dated June 16th, states that satisfactory experiments have been made with a new method of inoculation discovered by Dr. Edington.

Clinical Department.

A CASE OF CÆSAREAN SECTION.¹

BY EDWARD REYNOLDS, M.D.

MRS. P., thirty-two years old, married, a native of Cambridge, was brought to me when about six months advanced in her third pregnancy, by Dr. L. E. Morgan. Her first labor, which occurred in 1886, was under the charge of Dr. Nichols, of Cambridge, who, with the assistance of Dr. Driver, succeeded in safely delivering her; but only after a prolonged and difficult forceps operation, and at the sacrifice of the life of the child and the integrity of the soft parts of the mother. Her second pregnancy, a year later, was again under the charge of Dr. Nichols, and was wisely terminated by the induction of labor at eight months. Even at this period, however, forceps were again necessary, and a living child was extracted only after a prolonged and difficult operation.

Nearly ten years had elapsed without pregnancy, when the patient finding herself again in this condition, placed herself in Dr. Morgan's hands, told him her history, and informed him that her former attendants had advised her never to go beyond seven months. Dr. Morgan communicated personally with both Dr. Nichols and Dr. Driver, and was emphatically advised by both of them not to undertake a labor at eight months.

Dr. Morgan and I measured the pelvis together, at about six months, with the following results: Distance between anterior superior spines of the ilium 22½ cm. (9 in.); distance between crests of ilium, 26 cm. (10¼ in.); external conjugate, 20 cm. (8 in.) diagonal conjugate 4 in.; true conjugate, by estimation, 3½ in. or perhaps a little less; form of deformity, justo-minor. We agreed to see the patient together at intervals of a fortnight and decide upon the course to be pursued in accordance with the development of the child. At seven months the child was small, and the head evidently bore no relation to the size of the pelvic brim, being easily moved from side to side when pressed into the brim by pressure from above. We then told the patient that an induction at that time would probably result in the loss of the child and was unnecessary for her own sake. Both she and her husband stated that they estimated the life of the mother at so much higher value than that of the fetus that they were unwilling to consider the latter in comparison with the slightest increase of risk for the mother; and they consequently consented very unwillingly to a further prolongation of the pregnancy. I now saw the patient at weekly intervals, but even at eight months the child was very small, and entered the brim on pressure from above so extremely easily, that I was unwilling to admit that the time for an induction had come; but recognizing the ease with which one may be mistaken in the size of the child *in utero*, I was unwilling, in view of the history of the preceding labors, to attempt an intrapelvic labor at a period later than eight months. I therefore recommended the Cæsarean section at term, on the ground that it was the safest thing for the child; and upon the whole, safer for the mother than an induction of labor at any latter period, with the chance that this might be followed by a difficult forceps operation. The patient being thoroughly unwilling to accept this decision, I

² Dr. Williams, of Denison, Tex., in 1880 (Harris).¹ Read before the Obstetrical Society of Boston, February 16, 1897.

advised her to see some other obstetrician and obtain his advice, without telling him what mine had been. Mrs. P. accordingly consulted Dr. George Haven, who gave her the same advice. This joint decision was accepted by the patient and her last catamenia having occurred on the 5th of December, the date for the operation was set for September 10th, unless labor should occur earlier.

This did not happen, and the operation was performed shortly after 11 A. M. on that day. The abdomen was opened by an incision about eight inches in length in the median line. The uterus was lifted through the incision, surrounded by towels and the cervix grasped by the hands of an assistant. The uterus was then opened in the median line by an incision about six inches long. The arms and legs presented. The child was extracted by traction on the legs, and cried much more promptly than most Cesarean babies do. The placenta was implanted on the fundus and left lateral wall, its edge just appearing in the wound. The placenta was calcareous and with the membranes was universally adherent to the walls, but owing to the accessibility of the uterus under these circumstances, could be very rapidly dissected off with the fingers. Half a drachm of Squibbs' fluid extract of ergot was given hypodermically. The uterus contracted well. Ten braided silk intermuscular, and six fine silk sero-serous sutures were inserted and tied, after a bit of gauze had been passed into the vagina through the cervix. Fifteen silkworm-gut, and a number of finer coaptation sutures were used in the abdominal wall. The abdominal incision and the delivery of the uterus occupied three minutes; the uterine incision and the delivery of the child, one minute; the delivery of the adherent placenta, two minutes; the total time of operation to this point being six minutes. The uterine suture occupied $8\frac{1}{2}$ m.; the abdominal suture, $20\frac{1}{2}$ m.; total time of operation $40\frac{1}{2}$ m. The recovery from ether was rapid. There was no vomiting and little or no thirst. The temperature for six days ran between 100° and 101° , no explanation of its elevation being found except that the patient was in an extremely nervous state. There were no other symptoms of any kind whatsoever. The patient was kept in bed for three weeks to secure good involution of the abdominal walls, and was discharged in first-rate condition at the end of four weeks. Her baby was a girl, weighing eight pounds and one ounce, was nursed from the start, and reached a weight of one and a quarter pounds above its birth weight during the first four weeks, weighing nine pounds and five ounces on discharge.

I heard the other day that mother and child are both in the best of health.

I report this case as another instance of the elective Cesarean section, and in support of the position which I hold to be the proper one at the present day, that while there is still a field for the induction of labor, the Cesarean section is to be preferred, in the interests of the child, to the induction of labor for contracted pelvis at a period earlier than eight months, and in the interests of both mother and child to an induction at eight months or a later period, under circumstances which render it likely that the induction will be followed by a difficult labor.

There are two other points which I have noticed in every Cesarean section which I have done or seen, and which I mention in connection with this report

only because I have never seen them referred to in any published report of Cesarean cases:

First, I have noticed that the babies when first extracted appear sluggish, and usually require considerable stimulation before they breathe, cry, or move with any activity. It would seem probable that this sluggishness is due to the fact that their intra-uterine life is so suddenly and gently interrupted, and that a certain amount of handling, hot and cold water, and other cutaneous stimulation is needed to replace the disturbing and stimulating effects of the normal passage through the pelvic canal.

Second, it appears to be the rule that there is little or no lochia during convalescence from the Cesarean operation. This I offer simply as an observation, and one which I should be glad to have explained.

CASE OF SYMPHYSEOTOMY.¹

BY E. H. POMEROY, M.D., CALUMET, MICH.

Mrs. C. M., mixed Indian and Canadian French blood, rachitic dwarf, age twenty-one, height four feet, five and a half inches. First pregnancy. Married October, 1895. Last menstruation last week of December, 1895. Labor commenced during the night of November 2, 1896. As this was a case of elective symphyseotomy, I had taken the following pelvic measurements several weeks before: spinous processes, $10\frac{1}{2}$ inches; crests, 10 inches; diameter of Baudelocque, 7 inches; internal diagonal conjugate, $2\frac{3}{4}$ inches; true conjugate (estimated) 2 inches.

Early on the morning of November 3d, in the presence and with the assistance of my associates of the Calumet and Hecla Hospital Staff, Drs. Niles, Simonson, Bobb, Shorts and Rees, I performed symphyseotomy. The patient was first rendered surgically clean, as for a capital operation. I regret that I cannot recall the name of the operator whose directions I followed in separating the symphysis. The principal portion of the operation consisted in a short incision, half an inch in length, directly through the soft parts covering the middle of the anterior aspect of the symphysis; the section with a tenotome of all the symphysis excepting about three-eighths of an inch of the upper portion; then the insertion of a probe-pointed bistoury beneath the soft parts and close to the symphysis, until it could be made to hook over the upper, unsevered portion of the latter, meeting the end of the finger of the left hand, which finger has been thus far held constantly and steadily as a guide and guard against the inner aspect of the symphysis; with this knife the remaining portion of the symphysis was separated. The forceps were then applied and traction made until the pelvic bones separated and the fetus, a large and vigorous male, was delivered. During the delivery, although the ilia were supported strongly by an assistant pressing from each side, the pubic bones separated a distance of fully two and a half inches, and both sacra-iliac articulations gave way with sounds perceptible, if not alarming, to all the physicians present.

The child had the appearance of having grown nearly ten months *in utero*. I regret that no accurate mensuration of the fetus was made. It was weighed by Dr. Bobb, and the weight was slightly more than

¹ Reported, by invitation, before the Obstetrical Society of Boston, February 16, 1897.

twelve pounds (twelve and a half pounds including the cloth in which it was suspended; the subsequent weighing of the cloth made no impression on the small spring-scale used).

A small tear in the perineum was immediately repaired; a warm sublimated intra-uterine douche given; the original incision, as well as a tear half an inch long near the fourchette, dusted with boric acid and iodoform; a voluminous padding of sterilized dressings applied; broad bands of rubber adhesive plaster encircling the pelvis; the knees and ankles padded and bandaged to their fellows, and a broad obstetric binder applied. The bandage of adhesive plaster was soon found to be inefficient to hold the pelvic bones in proper position, and a belt of surcingle web, with strap and buckle, was added, and found to retain the bones in position admirably.

These dressings, and the horizontal position, were insisted upon for three weeks, although lying on either side was allowed. Recovery was uneventful, excepting for an occasional rise of temperature, which would yield immediately on the use of a boiled-water or mild sublimate douche.

At the end of three weeks, firm union was found to have taken place at both sacro-iliac junctures and at the pubic symphysis. The patient has been wholly free from restraint since the fourth week (present writing March 11, 1897); lactation has been free and normal from the beginning; and the child is a typical specimen of vigorous health.

This is the only case of symphyseotomy I have ever seen. The only Cæsarean section I ever saw was before the era of asepsis. The results of my symphyseotomy have been very pleasing. The union of the pelvic bones remains firm and strong. The patient leads a laborious life as a miner's housewife, walks long distances in deep snow, apparently without fatigue, and expects to raise a large family of children.

Cæsarean section, however, as described in the report of Dr. Reynolds's case, and in Dr. Worcester's approved comments, is a better surgical operation, cleaner, simpler, gentler; and listening to the report certainly gives me a more pleasing impression than I ever experienced from my own case of symphyseotomy, although I believe the record of statistics to be more in favor of symphyseotomy. In due time I expect to attend my patient in a second delivery, which I purpose shall be a Cæsarean section, and in a third which shall be an elective operation, based upon the experience of the first and second.

Reports of Societies.

THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., SECRETARY.

REGULAR Meeting, February 16, 1897, the President, DR. FRANCIS H. DAVENPORT, in the chair.

DR. EDW. REYNOLDS reported

A CASE OF CÆSAREAN SECTION.¹

DR. G. J. ENGELMANN offered

REMARKS ON SYMPHYSEOTOMY.²

DR. E. H. POMEROY of Calumet, Mich., reported

A CASE OF SYMPHYSEOTOMY.³

DR. J. P. REYNOLDS referred to the importance, in collecting statistics of the two operations, of comparing only those that are done by experts. It is manifestly unfair to compare the operation of symphyseotomy, for example, performed by an expert, with Cæsarean section done by a general practitioner.

DR. A. WORCESTER said that as a general practitioner he felt strongly the ease with which Cæsarean section could be done, as compared with symphyseotomy. He believed that the latter operation required more surgical skill to avoid complications.

In our statistics all deaths from septicemia, which are avoidable, should be thrown out.

DR. E. REYNOLDS, in closing, said that the keynote was struck by Dr. Engelmann when he said that symphyseotomy did not compete with Cæsarean section at the time of election, but that it was the operation to be used at the latter part of a long labor, where the patient was exhausted and the soft parts lacerated. In these cases Cæsarean section often proved very fatal.

He would agree with Dr. Worcester that Cæsarean section was the simpler operation for the inexperienced surgeon, but this operation should never be done by the man who did not appreciate thoroughly the meaning of asepsis. For the dirty-fingered man craniotomy was the only operation.

He mentioned two observations he had made in his experience with Cæsarean section. One was that if the operation was done before the onset of labor, the cervix would dilate and stay dilated on the removal of the child. This overthrew the bugbear that one could not get good drainage unless labor had started up. The other observation was that the lochia were of very small amount and duration after Cæsarean section.

THE AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

ELEVENTH ANNUAL MEETING, WASHINGTON, D. C.,
May 4-6, 1897.

FRANCIS S. WATSON, M.D., President, occupied the chair.

FIRST DAY. — TUESDAY.

REPORT OF POST-MORTEM EXAMINATIONS IN SOME CASES OF MOVABLE KIDNEY.

DR. FRANCIS S. WATSON, of Boston, read a paper on this subject. It consisted of a report of the post-mortem findings in eight cases of movable kidney. Four of these subjects were females, four males. In four of them both kidneys were movable; the right kidney alone was movable in three cases; the left kidney alone in one case. The perinephritic fat was greatly diminished in five cases and slightly diminished in two; it was not noted in one. Hydro-nephrosis was absent in all of the cases. There was ptosis of one or more of the other abdominal organs in six cases; none in two. The peritoneal coverings of the kidney were greatly relaxed in four cases; in four they were moderately relaxed. In two of the first four cases, those in which the peritoneum was greatly

¹ See page 35 of the Journal.

² See page 34 of the Journal.

³ See page 36 of the Journal.

relaxed, the kidney rotated upon its long or short axis upon turning the body on the side opposite to that of the mobile kidney or raising it to an upright position and then bending it far forward. In two others of this group these movements of the organ were prevented by the presence of a number of transverse bands of peritoneum which occurred at short intervals, and which were all that restrained it. In none of them was there any evidence of dilatation of the pelvis or the calices of the kidney, or of any organic change that could be referred to the presence of a hydronephrosis during life; and this was as true of those in which the condition was of long standing, and the motility very marked as in the others. This fact, Dr. Watson said, he had also observed in five other cases in the living subject on whom he had performed nephrorrhaphy. His observations in these 13 cases confirmed the view recently expressed by Albarran, that at least in the earlier stages of movable kidney the enlargement of the organ so often noticed in connection with the crises is due to acute congestion rather than to retention of urine in the renal pelvis and subsequent dilatation.

CLINICAL OBSERVATIONS ON LOOSE AND DISPLACED KIDNEY,

by DR. JOHN P. BRYSON, of St. Louis.

These observations, the speaker said, had been made in the course of operative work in this field. The real pathological entity in the condition of loose or displaced kidney, in his opinion, was a disturbance in the fatty capsule: whether or not this was accompanied by a more or less general euteroptosis he could not say. There exists, so far as he had been able to observe, first, a loosening of the capsule, which allows the kidney to move about within it; second, the capsule itself may become loosened from its posterior and superior attachments in such a way as to slip about with the kidney; third, these abnormal conditions may be combined in a greater or lesser degree.

He had noticed as a common occurrence that the pain in the neighborhood of the kidney was in inverse proportion to the amount of motility of the organ in the earlier stages. He reported a case of movable kidney on the right side, accompanied by marked gastric disturbance. The latter symptom he had never observed in connection with disturbance of the left kidney, whether due to calculus or other cause, while with disturbance of the right kidney vomiting was very common. This fact, to his mind, suggested some anatomical connection between the right kidney and the pneumogastric nerve. The speaker said that so far as he had observed, a good deal of the pain and distress which accompanies these cases of loose kidney is due to the relative looseness and length of the vascular pedicle.

DR. J. WILLIAM WHITE, of Philadelphia, referred to the relative frequency of movable kidney in women. Among the etiological factors of the condition he mentioned pregnancy, tight lacing and a disappearance of the fat due to some exhausting disease. In the production of the symptoms, hysteria or the neurotic element possibly played some part. The gastro-intestinal symptoms which accompany right movable kidney, he thought, were explicable on mechanical grounds, and were due to disturbance of the duodenum by the displaced kidney.

DR. EDWIN C. BURNETT, of St. Louis, said he had

observed a case of renal calculus on the left side in which vomiting occurred after the crisis.

DR. EDWARD MARTIN, of Philadelphia, said that recent anatomical researches help to explain why the kidney maintains its position. Cross-sections show that the organ is, to a certain extent, shelved, together with its fatty capsule.

DR. EUGENE FULLER, of New York, said that in some cases of painful kidney, simply disturbing the capsule seems to effect a cure. He thought many kidneys were movable with reference to the outer layer of the fatty capsule, no matter whether the kidney itself is movable or not; they are not true movable kidneys.

DR. JAMES BELL, of Montreal, said he was particularly interested in the fact that hydronephrosis is comparatively infrequent in movable kidney. He had only observed two cases where this was a marked complication.

DR. JAMES P. TUTTLE, of New York, mentioned an observation made by Dr. Janeway, that the more movable the kidney the less severe the renal symptoms, while the gastro-intestinal symptoms seem to be correspondingly increased.

DR. BRANSFORD LEWIS, of St. Louis, referred to a case of pyelitis of the left kidney where after each crisis the patient suffers from intense nausea — sometimes vomiting.

SOME OBSERVATIONS UPON THE SURGICAL ANATOMY OF THE KIDNEY.

DR. GEORGE E. BREWER, of New York, read a paper with this title. It was based upon numerous examinations made during the past summer to determine the frequency, causation, symptomatology and treatment of movable kidney. The total number of cases examined was 351. Of these 200 were clinical and 151 were post-mortem examinations. Of the 200 clinical examinations, 142 were males and 56 females. The total number of displaced kidneys found in the 200 clinical examinations, was 11, or 5.5 per cent., of these, nine were reported as palpable, one movable and one floating. In the 142 males, displacement of the kidney was found but twice; in both instances it was the right kidney, and was recorded as palpable. The percentage, therefore, of displaced kidney found in the males examined was 1.4 per cent. In the 56 females examined, displacement of the kidney was noted in nine instances, or 17.3 per cent., of these, seven, or 12 per cent., were recorded as palpable; one, or 1.7 per cent., as movable, and one, or 1.7 per cent., as floating; all occurred upon the right side. Of the eleven patients in whom movable kidney was found, only one complained of symptoms which could be attributed to the displaced kidney, and that was a case of floating kidney in a very hysterical female.

Regarding the accuracy of these observations, Dr. Brewer said that in every case recorded as palpable, movable or floating kidney, he firmly believed that the kidney was felt; that a number of displaced kidneys may have escaped detection he regarded as highly probable, as in many instances, owing to the rigidity of the abdominal muscles, or an excessive deposit of fat, it was utterly impossible to approximate the two examining hands sufficiently to appreciate the presence of an organ of the size of an ordinary kidney, and the only sensation conveyed to the fingers was a purely negative one.

Post-mortem Examinations. — Total number of subjects examined, 151. Of these, 91 were males, 56 females, and in four the sex was not recorded. The upper border of the right kidney was found opposite the eleventh rib in 78 cases. The upper border of the right kidney was found opposite the twelfth rib in 62 cases; in eight cases it was found one inch below the twelfth rib, and in one case one-half inch below the twelfth rib. The upper border of the left kidney was found opposite the eleventh rib in 100 cases, and opposite the twelfth rib in 43 cases; in one case it was found opposite the tenth rib, and in the five remaining cases it was found from one-half to one inch below the twelfth rib. One right kidney had been removed; and in one case the left kidney was congenitally absent.

If we consider all kidneys occupying a position below the free border of ribs as pathological, the number of displaced kidneys found upon post-mortem examinations of the 151 subjects was 14, or 9.2 per cent.; 10 of these occurred in males and four in females. Of the 10 occurring in males, six were on the right side and four on the left. Of the three in female subjects, two were on the right and one on the left.

Dr. Brewer said that the number of observations contained in the above record is far too small to enable one to draw any accurate conclusions from their analysis. The fact that the kidney may be firmly fixed in its normal position after death by no means proves that was not freely movable during life.

Before concluding his paper, Dr. Brewer called attention to a number of anatomical anomalies connected with the kidneys which were observed during the course of the post-mortem examinations, and which were of considerable surgical interest. This is especially true of the great variation found in the distribution of the arteries to the kidney; 85 of the kidneys received more than a single arterial trunk; 70 received two arterial trunks from the aorta, 12 received three, two received four, and one received five. Three of the latter were from the aorta, one from the ovarian, and one from the common iliac. Considerable variation was also observed in the arrangement of the renal, supra-renal and spermatic veins. A surprising number of variations in the ureter were also observed.

After concluding his paper, Dr. Brewer exhibited a number of photographs illustrating anatomical anomalies of the kidney.

DR. BANGS said that, while making some observations on the kidney in the dead-house at Bellevue two or three years ago, he came across some of the anomalies mentioned by Dr. Brewer.

DR. SAMUEL ALEXANDER, of New York, mentioned a case where the kidney was found to have an anomalous arterial supply. The condition was encountered during a nephrectomy, and fortunately recognized before any damage was done.

DR. BRYSON said that with some of the malformations of the kidney and ureter mentioned by Dr. Brewer, symptoms might have existed during life which would have proved very misleading.

DR. EDWARD MARTIN said that Dr. Brewer's difficulty in palpating the normal kidney was in accord with his own experience. Both with and without ether he had been unable to make out the kidney excepting in a very small proportion of cases.

DRS. WATSON and BANGS expressed similar views. RESULTS AFTER NEPHRECTOMY FOR RENAL TUBERCULOSIS.

DR. L. BOLTON BANGS, of New York, said that in order to learn the remote results of nephrectomy for renal tuberculosis, and compare them with the results of hygienic measures, he had collected, from literature and other sources, 112 cases, the majority of which had not been included in any previous report on this subject. His investigations extended back to 1888, when Newman made his report. Since then our methods of diagnosis in these cases have been vastly improved by the aid of the cystoscope and ureteral catheterization. One serious objection encountered was that in a certain number of the cases the remote history could not be ascertained, while in other instances the reports were so vague that no definite conclusions could be drawn.

The mortality from the operation in the 112 cases collected was about 19 per cent.; adding to this those that died within a few months after the operation, we get a mortality of a little over 28 per cent. These figures agree very closely with those of Pollet, who placed the mortality at 29 per cent.; 33 of the 112 cases, that is, about 30 per cent., survived for a period varying from one to eight years after the operation; 33 were reported as "promising"; in 19 there was no remote record of the patient.

The immediate result of nephrectomy for tuberculosis of the kidney, Dr. Bangs concluded, may be regarded as brilliant, and the prognosis as to the future promising, especially if the affection is of brief duration and confined to one kidney.

DR. CHISMORE said he favored the hygienic treatment of renal tuberculosis in preference to the operative.

DR. EUGENE FULLER said that while he agreed with Dr. Chismore, yet there are cases of this affection where the symptoms become unbearable and where an operation must be performed to give relief.

DR. ARTHUR T. CABOT, of Boston, spoke of the possibility of an error of diagnosis in these cases, owing to the close similarity between the smegma and tubercle bacillus. He referred to a case of supposed renal tuberculosis, the tubercle bacilli having been reported as present in the urine, which upon operation proved to be one of stone in the kidney.

DR. BRYSON mentioned a case of renal tuberculosis wherein repeated examinations failed to reveal the presence of the tubercle bacilli in the urine: this was afterwards found to be due to the fact that the ureter from the affected kidney was blocked.

DR. WATSON said he preferred the hygienic to the operative treatment, if the latter could possibly be avoided.

DR. BANGS, in closing the discussion, said that in the histories of the cases included in his report, frequent references were made to the smegma bacillus, and in some instances the diagnosis had been confirmed by cultures. In many of them the condition of the kidney was clearly tuberculous.

DETECTION OF STONE IN THE KIDNEY.

DR. EDWARD MARTIN, of Philadelphia, read a paper on this subject. He stated that in making the diagnosis of kidney calculus, the following points should be considered: family history; age and environment;

traumatism; diathesis; kidney lesions, whether obstructive or otherwise; the presence in the urine of mucus, blood, crystalline deposits, pus, epithelium or albumin; alternations in the quantity and specific gravity of the urine; pain; tenderness on deep palpation; tumor; gastro-intestinal disturbance; reflex disturbances of the lower urinary tract; palpation; ureteral examination; x-rays.

After reviewing in detail the symptoms and signs above enumerated, Dr. Martin said he should place in the order of value:

(1) X-ray photographs; of these, several should be taken, with the light placed somewhat differently, before their negative evidence is accepted.

(2) The passage of gravel or small concretions, associated with renal hematuria, fixed pain and colic.

(3) Renal hematuria, aggravated by exercise, markedly relieved by rest, remaining long unassociated with pyuria.

After concluding his paper, Dr. Martin exhibited a number of negatives of x-ray photographs, one of which quite distinctly showed the presence of a stone in the kidney.

DR. BANGS said the diagnosis of kidney stone was sometimes very obscure, and any new method to aid us should be warmly welcomed. Thus far he had not had very satisfactory results from the use of the x-rays. Mere puncture of the kidney in cases of suspected stone is not always conclusive.

DR. FULLER said the majority of cases of renal calculus which give rise to marked symptoms are those where the stone is small, but too large to enter the ureter, and in such instances he did not think the x-rays would prove of much service.

DR. BRYSON agreed with Dr. Fuller, that the small calculi are the ones more apt to cause trouble.

DR. CHISHOLM advised flushing out the kidney in order to remove small particles of stone.

DR. CABOT mentioned a case where the entire kidney pelvis was found to be filled with a gravelly mass made up of triple phosphate crystals and held together by tenacious mucopus. In that case four attempts had been made to get a photograph by means of the x-rays, but the results were negative.

DR. BRANSFORD LEWIS, of St. Louis, exhibited

A MODIFIED SCROTAL RESECTION CLAMP.

DR. PAUL THORNDIKE, of Boston, reported

A CASE OF CYSTIN CALCULUS IN THE MALE BLADDER.

The calculus weighed three and one-half grains. The case was of interest because of the rarity of this kind of stone, and because of the fact that it was only after repeated examinations that cystin crystals were found in the urine. The urine usually had a very disagreeable odor, due to the evolution of sulphuretted hydrogen gas.

(To be continued.)

THE CONSUMPTION OF TOBACCO. — The annual consumption of tobacco in Holland is a little over 7 pounds a head; in the United States, 4.5 pounds; in Austria, 3.8 pounds; Denmark, 3.7 pounds; Switzerland, 3.3 pounds; Belgium, 3.2 pounds; Germany, 3 pounds; Sweden and Norway, each 2.3 pounds; France, 2.1 pounds; England, a little under 2 pounds; Italy, Russia, Spain, 1.25 pounds. It is estimated that 2,000,000,000 pounds weight are used annually, of a money value of more than \$2,500,000,000.

AMERICAN MEDICAL ASSOCIATION.

ABSTRACT OF THE PROCEEDINGS OF THE SECTION ON PRACTICE OF MEDICINE, PHILADELPHIA, JUNE 1-4, 1897.

(Concluded from No. 1, p. 18.)

THE papers presented by DR. DE SCHWEINITZ, of the Department of Agriculture at Washington, on

TUBERCULOSIS, ANTITOXIN AND ANTITUBERCULIN, which DR. MCFARLAND read, were brief. The latter's experiments with small animals by inoculation were interesting.

HOW TO TREAT TUBERCULOSIS.

DR. D. L. ROCHESTER, of Buffalo, made a report on this subject. After referring to a number of cases he had treated for tuberculosis, and the success or failure attendant, Dr. Rochester laid great stress upon the importance of properly conducted exercise in the treatment of pulmonary tuberculosis. Without exercise and fresh air all efforts come to naught, regardless of whatever specific medication is used, he declared. The treatment of special symptoms was thus advised:

Cough. — Generally best relieved by attention to the upper air-passages, keeping them free from secretion. The constant inhalation of essence of peppermint through a perforated zinc mask was especially valuable.

Pain in the Chest was best relieved by strapping the chest, or by hypodermic injection of morphine.

Fever. — Best controlled by the nuclein administration. Sponging with alcohol and water is often of great value.

Sweating. — This generally disappears during the treatment with nuclein. Atropine and aromatic sulphuric acid still remain at the head of the list of drugs useful in controlling this distressing symptom.

A further report on

THE TREATMENT OF TUBERCULOSIS BY IODOFORM INUNCTIONS

was made by DR. L. F. FLICK, of Philadelphia.

He had met with only varying success. In discussing the disease Dr. Flick expressed the opinion that the profession were too proud to speak of cases of tuberculosis as being cured, when in fact they were only improved. In many cases the disease reappeared after a long interval.

DR. S. SOLIS COHEN, of Philadelphia, coincided in many points with the author of the paper. Before the Section adjourned to attend the general session, Dr. Cohen exhibited an apparatus for the inhalation of compressed air and exhalation into rarefied air, used in cases of tuberculosis and other diseases of the lungs.

CURABILITY OF PULMONARY TUBERCULOSIS

was presented in a paper read by DR. E. B. BORLAND, of Pittsburg.

Evidence has been accumulating which shows that tuberculosis is not only a universal, but the universal disease, said he. Post-mortem examinations made in recent years point to the probability that 25 per cent. is much too low an estimate of the total number of infections. Schlenker made 100 consecutive post-mortem examinations of children and adults for this purpose, and found 66 per cent. tuberculous. Turn-

ing to pulmonary tuberculosis, Babes found lesions of the bronchial gland in more than one-half of his post-mortems on children. Long before Koch discovered the tubercle bacillus, Louis laid down the rule, that, if tuberculosis was found in any part of the body, it would be found in the lungs.

It will be a moderate estimate to say that nearly 50 per cent. of the human race are infected at some period of life with tuberculosis. Large as is the death-rate, the tubercle bacillus does not seem to be a markedly virulent germ. Without the addition of septic germs pulmonary tuberculosis would not be the fatal disease it is to-day. The vile habit which American people have of expectorating on floors and sidewalks has much to do with the transmission of septic germs, as well as tubercle bacilli, to the lungs.

Nature can wall up tubercle bacilli with bodies of leucocytes and connective-tissue cells for life, but cannot imprison septic germs for any great length of time. Tuberculosis uncomplicated with sepsis may be considered a curable disease, in the sense that it may be held in abeyance, that is, kept in a latent condition, for a lifetime, providing the vital resistance of the individual is kept up to the normal standard. Nature has been known to completely eradicate it in a limited number of cases. The scientific physician will endeavor to imitate nature so far as he can interpret her methods.

The question arises, Can tuberculosis be cured to all intents in its latent stage? It has been demonstrated that two-thirds of all infectious diseases either disappear or remain quiescent during an average life. If nature can accomplish so much under the reign of empirical medicine, what will she be able to do when the physician concentrates all his energy on building up and maintaining the vital resistance of cell life, and keeping septic germs away from the latent life. The author has nothing to offer on the curability of the ulcerative stage, that is to say, the well-developed mixed infection. Perhaps less than three per cent. throw off both infections and fully recover. In probably 20 per cent. the disease becomes quiescent, and remains so for a number of years, and is then lighted up again. The average life of the remaining 77 per cent. may be placed at two years. The posting and enforcing the placard: "Gentlemen *will* not, others who do not class themselves under the title *must* not, expectorate on floors and sidewalks," would do more to improve the prognosis of either stage of pulmonary tuberculosis than all the toxin or antitoxin treatments of the last decade.

A general discussion on tuberculosis followed, which was opened by DR. CHARLES DENISON, of Denver, Col. He was hopeful that in the future a specific would be discovered which would be effective in the cure of this dread disease. Others who participated in the general discussion were DRs. HERRICK, KLEBS, ROCHESTER, PAQUIN and FLICK. Several thought an absolute cure absolutely impossible.

DR. WOODS HUTCHINSON, of Buffalo, spoke of deformities of the chest in the light of ancestry and development. He placed all chests in two classes. Chests of animals as well as humans were represented by illustration with explanatory remarks.

THE TREATMENT OF CROUPOUS PNEUMONIA,

was the subject of a paper by DR. D. S. CAMPBELL, of Detroit.

Cold applications were regarded by the speaker as extremely effective. Their use had enabled him to save many lives in private and hospital practice.

DR. J. EICHBERG, of Cincinnati, O., read a paper on THE HOT BATH IN THE TREATMENT OF PNEUMONIA.

As practised in the hospitals of that city the temperature of the hot baths is generally 100°. The patient is wrapped in a warm blanket after emerging from the bath, and kept there for a period of half an hour before the body is subjected to a vigorous rubbing. The most powerful argument in favor of the bath was the fact that patients at first averse to taking the bath soon expressed a desire for its repetition, even before the proper time for giving the bath had arrived. The case of a butcher who had suffered for twenty-one days was mentioned. In that interval he was given 137 hot baths, and finally recovered.

DR. N. S. DAVIS, JR., of Chicago, read a paper on CHEYNE-STOKES RESPIRATION.

The session adjourned after a brief discussion following the reading of a paper by DR. ALLYN on

MULTIPLE NEURITIS IN INFLUENZA.

FOURTH DAY. — FRIDAY.

The following resolution was offered and adopted:

Resolved, That Professor Welch, of Baltimore, and others who took part in the discussion on Sero-Diagnosis, be appointed a committee to draw up a brief statement of the consensus of opinion arrived at through this discussion, this statement to be published in the journal of the Association in connection with the report of the discussion.

The other members of the committee are Dr. Wyatt Johnston, of Montreal; Drs. Cabot and Richardson, of Boston; Dr. Black, Baltimore; Dr. Biggs, New York; Drs. Kneass, Swan and Musser, Philadelphia; Dr. N. S. Davis, Jr., Chicago, and Dr. Ohlmacher, Cleveland.

An extended discussion on

GOUT

ensued, in which a dozen physicians were announced to participate.

DR. WOODS HUTCHINSON, of Buffalo, opened the discussion. He spoke extemporaneously. A strict diet, plenty of exercise and abundance of the best tonics obtainable were prescribed by the speaker as the remedy for this ailment.

DR. CHARLES STOCKTON, of Buffalo, presented a paper on the "Gastro-Intestinal and Hepatic Relations and Manifestations of Gout." Murchison and Sir Dyce Duckworth, among other students of the subject, he said, had associated the excessive formation of uric acid and the development of gouty attacks with disturbances of the liver. Under the name of lithemia, or latent gout, Murchison described a set of symptoms very commonly met with in this country. Among the conspicuous symptoms are the appearance of uric acid, urates and calcium oxalate crystals. These cases of lithemia show evidence of disturbed primary digestion, headache, lassitude, malaise.

Let us return to the question propounded, continued the speaker, Is lithemia gout, or is it the expression of a toxemia resulting from habitual disorder of the digestive organs, including the liver? From experience the conclusion has been forced upon me that the great majority of instances of so-called lithemia are,

in fact, cases of toxemia in no true sense gouty in nature. In conclusion, I would say:

(1) That gout is a definite disease, to which certain individuals are predisposed, but which depends for its development upon causes largely unknown.

(2) Laziness and full nitrogenous diet and the use of fermented liquors predispose to the disease.

(3) So-called lithemia, as the term is popularly applied, is not gout, but it is an auto-intoxication, depending upon gastro-intestinal derangements.

(4) The diet in gout should be largely free from nitrogenous substances.

(5) The diet in lithemia must be ascertained by a careful study of the primary digestion and the general health of the patient.

Further papers on Gout were read by DR. T. B. FUTCHER, of Baltimore, and DR. CHAS. A. OLIVER and F. S. PEARCE, of Philadelphia. The general discussion of the topic was abbreviated by the absence of quite a number of the speakers announced.

DR. H. C. WOOD, of Philadelphia, declared that the treatment for the disease was not so necessary as the treatment of the individual. He advocated a meat diet generally.

There was considerable applause when Dr. Wood said that the bicycle was the greatest antilithic in the world. If there was any cure for gout, exercise would come nearer effecting it than anything else.

Every man who has had a gouty grandfather, said he, should take a Turkish bath at least once a week. You can't wipe out ancestral traces any other way.

The discussion of

ANEMIA,

scheduled for Thursday, and made a special topic for yesterday, was begun at noon.

Owing to the illness of Dr. Stengel, DR. A. E. TAYLOR opened the subject assigned to Dr. Stengel, "The Nature and Varieties of Anemia." Dr. Taylor also read a paper prepared by himself, on "The Alterations in the Blood and the Methods of Determination."

The other contributors to the subject were DRs. S. M. HAMILL, D. L. EDSALL and W. CAMPBELL POSEY.

An adjournment was taken at one o'clock to enable the Section to attend the luncheon at the Aldine, tendered by the Philadelphia Medical Club.

Three papers by DR. D. D. STEWART were read by title.

Papers were also presented by DRs. EINHORN, of New York; WILLIAMS, of Buffalo, and DR. JAMES TYSON.

The proceedings of the session of the afternoon proper were exceedingly brief.

THE TREATMENT OF CARCINOMA BY A NEW METHOD, was discussed by DR. G. B. MASSEY.

DR. J. D. STEELE described his

METHODS OF TREATING A CASE OF PRIMARY RENAL TUBERCULOSIS.

DR. MATTHEW WOOD's experiences in

TREATING EPILEPSY BY THE NIEMEYER METHOD were interesting.

The Section adjourned *sine die* after hearing a paper read by DR. KLINE, of Washington, D. C., on

MEDICINE AS AN EXACT SCIENCE.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JULY 8, 1897.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

HAFFKINE'S PLAGUE PROPHYLACTIC FLUID.

DR. HAFFKINE, in a letter to the *British Medical Journal*, gives an interesting account of the physical characteristics of the plague bacillus, of the method of preparing his prophylactic fluid, and the results from its use.

The plague bacillus may be recognized by its stalactite growth in broth.

Broth richly inoculated with the plague bacillus is placed in a perfectly quiet position. Twenty-four to forty-eight hours after inoculation, the liquid remaining limpid, flakes appear underneath the surface, forming little islands of growth. In the next twenty-four to forty-eight hours the flakes grow down in a long stalactite-like jungle, the liquid always remaining clear. In four to six days the islands of growth get more compact and solidified. If the flask is slightly disturbed, then the islands fall down to the bottom in a sort of snowfall, bringing down the stalactites, the whole growth getting deposited at the bottom. The appearance of the islands of growth underneath the surface is accompanied or preceded by the deposition of a residue on the sloped walls of the flask and at the bottom, as well as by the appearance of a ring round the surface of the liquid.

Characteristic also of the bacilli are its involution forms on agar-agar. The medium is not to contain glycerine, and is not to be freshly prepared, but must be partly desiccated, and have the surface perfectly dry, showing a good alkaline reaction. The germs are to be inoculated abundantly, and preferably spread over the whole surface of the agar in a continuous layer.

Rarely in twenty-four hours, as a rule, in three to four days, the individual microbes begin to swell up, and form large round or oval bodies, staining in the beginning well, afterwards showing colorless central regions, which extend gradually to the peripheral parts. The bacilli become unrecognizable, lose the

appearance of schizomycetic microbes, and acquire that of a yeast cell or alga. The swelling continues often to the extent of forming a body about twenty times larger in surface than the original bacillus. The power of staining is afterwards lost completely, and the remains of the microbe appear in the shape of an unrecognizable dusty spot.

These forms are not to be seen in liquid cultures, but I have discovered and demonstrated them in the tissues of inoculated rabbits. Their appearance in the tissues suggests at first the idea of modified blood corpuscles, or disintegrated tissue cells, or stained drops of albumin.

In planning for the preparation of his prophylactic fluid Haffkine was guided by the consideration that his cholera inoculation, which is made with the bodies of Koch's bacilli, reduces the susceptibility and absolute mortality of the disease, but not the case mortality. This result is believed to be due to the fact that it has a bactericidal and not an antitoxic action. Considering the possibility that the bactericidal properties resided in the bodies of bacilli, and the antitoxic power in the substances produced by them in the media in which they grow, Haffkine undertook to prepare a fluid containing both the bodies of the bacteria and the toxins.

Luxurious growths of plague bacilli are cultivated by adding to the nutritive media large amounts of fat exposed to free aëration. Clarified butter is suspended in the flasks of nutrient media, and successive crops of the bacilli having been grown, the liquid is shaken, by which a milky-white emulsion is produced, and then the bacilli are killed by exposure of the fluid to a temperature of 70° C. for an hour. In a quiet position in test-tubes two different substances are then obtained: a thick, white sediment and a perfectly limpid fluid. Injected subcutaneously into animals they produce: (1) the sediment, a local inflammation and a nodule at the seat of inoculation, accompanied with little fever or general effect; and (2) the fluid, a considerable rise of temperature and a general affection, with no noticeable local effects.

Inoculations with the mixed sediment and fluid were begun on January 30th at a house of correction in Byculla, Bombay, where plague had appeared among the prisoners, and continued until the epidemic ended on February 7th. The results may be summed up as follows: Total occurrences from the first day after inoculation till the end of epidemic — 12 cases, 6 fatal, in an average daily strength of 173 non-inoculated; 2 cases, none fatal, in an average daily strength of 148 inoculated.

"If repeated observations in similarly precise conditions," writes Haffkine, "confirm the results in the Byculla Goal, the plague prophylactic will appear to influence the disease in men in a very advanced stage of incubation, the period of the latter being in plague apparently between two and seven days, whereas the prophylactic will appear to act in some twelve to fourteen hours, arresting or mitigating the disease in individuals infected several days before. The rapidity of its effect would recall the immunity produced

in a few hours in animals by injection of non-fatal doses of comma bacilli into the peritoneal cavity.

"Between January 10, and May 6, 1897, 11,362 individuals from the infected areas have been inoculated by the above process with the following occurrences, which do not include those in the Byculla House of Correction detailed above.

"The fatal occurrences were 12, namely: 3 patients who were already unwell at the time of inoculation; 3 patients who contracted the disease within twelve hours after inoculation; 2 patients who fell ill within three days after inoculation; 4 patients attacked fifteen to twenty-five days after inoculation. The attacks with recoveries numbered 33.

"Figures relating to the general population are not available for an exact comparison with the death-rate from plague in the corresponding classes of non-inoculated persons. A rough estimate, however, would seem to show that the inoculated have suffered to an extent about twenty times smaller than the non-inoculated living under the same conditions and exposed to the same chances of infection."

MEDICAL NOTES.

A MILLIONAIRE IMPRISONED FOR SPITTING IN THE STREET-CARS. — W. B. Bradbury, a wealthy resident of San Francisco, Cal., is reported to have been convicted for the second time of spitting in the street-cars, and sentenced to twenty-seven hours' imprisonment in the county jail.

PHILADELPHIA POLYCLINIC. — Dr. T. B. Schneide-man, formerly adjunct professor, has been elected professor of diseases of the eye in the Philadelphia Polyclinic. Dr. G. Hudson Makuen, formerly lecturer, has been elected professor of defects of speech. Dr. C. W. Burr has resigned the professorship of diseases of the mind and nervous system.

AN INTERNATIONAL LEPROSY CONGRESS. — An International Congress on Leprosy is to be held in Berlin on October 11th. The following subjects for discussion are announced: "Pathological Anatomy," to be opened by Virchow; "Bacteriology," by Neisser; "Infectiousness," by Koch; "Etiology," by Besnier; "Diet in Relation to Leprosy," by Hutchinson. Numerous favorable responses have already been received by the committee, and it is believed that the attendance at the conference will be very large and representative of all countries and shades of opinion.

THE QUEEN'S JUBILEE FREE FROM ACCIDENTS. — Very few accidents occurred in London on the day of the Queen's Jubilee Procession, a fact which the *British Medical Journal* attributes to the perfection of the military and police arrangements, the absence of wheeled traffic, and the good humor of the crowd. Abundant ambulance service was provided, but the surgeons found little employment. Out of 47,000 troops only 25 fell out during the day, a fact which speaks well for the physical condition of the men.

PLAGUE AND THE PILGRIMAGE. — Official news from Jeddah confirms the announcement of the outbreak of bubonic plague in that town. The cases

stated to have occurred from June 5th to the 11th appear to have been few, and are said to have shown themselves in pilgrims that had returned from Mecca, and who were natives of Yemen, of Hadramut, of Abyssinia, and of Sudan. Mecca, however, and every other part of the Hedjaz, are stated to be free from plague. The Constantinople Board of Health was convoked on June 9th to propose measures for stamping out the outbreak in Jeddah, and for preventing it from spreading in the Ottoman dominions. The board decreed that cases of plague are to be placed in special isolated ambulances established for the purpose; that the clothing and the bedding of plague patients are to be destroyed by fire; that the houses in which cases of the plague have occurred are to be disinfected with a solution of corrosive sublimate, and whitewashed with lime, and then kept unoccupied for twenty days. A medical commission is to be sent to Jeddah from Constantinople to superintend this work. A sanitary cordon is to be established to prevent communications between Jeddah and Mecca.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, July 7, 1897, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 59, scarlet fever 22, measles 61, typhoid fever 3.

HEAT PROSTRATION.—Ten cases of heat prostration, with one death, were reported in Boston on July 5th, and fourteen cases, with three deaths, in New York.

GIFT TO THE SALEM HOSPITAL.—Mrs. W. G. Webb has given \$10,000 to the Salem Hospital to be used for founding a home for convalescents. The gift is in memory of her husband, who died last winter and who was for many years one of the trustees.

THE ADDISON GILBERT HOSPITAL.—The Addison Gilbert Hospital, at Gloucester, Mass., is finished, and has been opened for patients. In 1888 the late Addison Gilbert bequeathed \$100,000 for the establishment of a free hospital in Gloucester, for the poor of the city. The trustees may, however, receive in aid of its maintenance such compensation as patients may be able to pay. Mr. Gilbert also left \$75,000 for a Home for Aged and Indigent Persons. The hospital, which is a substantial and well-equipped building, is provided with an operating-room fitted up according to the requirements of modern aseptic work, an accident-room and a dispensary. The building cost about \$50,000; and the plans contemplate the construction of two wards in the rear, one for men and one for women, which will be built as soon as required. Twelve free beds have been provided for by private subscription.

NEW YORK.

PIER ROOF-GARDENS.—The first of the new pier roof-gardens was recently opened by the Mayor with appropriate ceremonies, and it will doubtless prove a

great boon to the poor. It is located at the foot of Third Street, near a densely crowded tenement-house population, and extends several hundred feet into the East River. As it is entirely covered over, it affords ample opportunity for mothers to bring their children to be in the shade and get the benefit of fresh air from the water. At night the pier is brilliantly lighted with electricity and a band plays for the amusement of the public.

PUBLIC SHOWER-BATHS.—At last the plans for the first permanent public baths have been completed, and the erection of the building will be at once commenced. It is to be located on Rivington Street, east of the Bowery, and will cost about \$70,000. For sanitary reasons it was decided to have no swimming pool, but there will be an abundance of hot and cold shower-baths. There will be accommodations for about two thousand persons a day, and the baths are to be kept open summer and winter. For those desiring to swim ample facilities are afforded by the fifteen free baths of the city located at convenient points along the Hudson and East Rivers, which are open during the summer season.

LEGACIES TO HOSPITALS.—By the will of Mayor Lehman, who died on June 21st, \$15,000 is bequeathed to the Mount Sinai Hospital, \$5,000 to the Montefiore Home for Chronic Invalids, \$3,000 to the Lebanon Hospital, \$2,000 to St. Mark's Hospital, and \$1,000 each to the German Hospital and the New York Orthopedic Hospital and Dispensary.

CENTENARIANS.—Mary Ryan, a native of Cork, Ireland, died in the almshouse hospital on Blackwell's Island on June 29th, at the advanced age of one hundred and five. At least, this is the age given on the death certificate sent to the Board of Health. Samuel Elsey, the oldest man in Erie County, and probably in the State of New York, died in North Evans, near Buffalo, on June 28th. He was born in London, England, November 7, 1790, and was, consequently, one hundred and six years and seven and one-half months old. He was a farmer, and had lived at North Evans for about fifty years.

DEATH OF WILLIAM C. WEY, M.D.—Dr. William C. Wey, one of the most prominent medical men in Western New York, died at his residence in Elmira on June 30th. He was born at Catskill, N. Y., in 1828, and was graduated from the Albany Medical School in 1849. He then removed to Elmira, and passed all his professional life there. For many years he was Health Officer of the city, and also President of the Board of Managers of the New York State Reformatory, located at Elmira. In 1871 he was elected President of the Medical Society of the State of New York.

WEEKLY MORTALITY.—With the advent of hot weather there has naturally been some increase in the mortality of the city. During the week ending June 12th the number of deaths reported reached the excessively low figure of 660. In the week ending June

19th the number of deaths was 711, in the week ending June 26th, 717, and in that ending July 3d, 831, an increase of 114. In the last-named week there were 135 deaths from diarrheal diseases, and the mortality in children under five years of age was 440, against 291 in the week ending June 19th. In the week ending June 26th three deaths were reported from sunstroke, the first of the present season. In the week ending July 3d there were two (2) deaths from this cause. The outbreak of small-pox seems to have been controlled, as there have been no deaths from the disease since the week ending June 19th, when three deaths were reported from it. During that week there were 43 deaths from diphtheria, the largest mortality for some time previous, but since then it has been less fatal, the number of deaths from it in the week ending June 26th being 27, and in the week ending July 3d, 25. The mortality from pulmonary tuberculosis has decreased from 95 to 78, and the deaths from pneumonia continue the same, averaging about 75 a week.

Miscellany.

AN ARMY MEDICAL BOARD

Will be in session at Washington City, D. C., during October, 1897, for the examination of candidates for appointment to the Medical Corps of the United States Army, to fill existing vacancies.

Persons desiring to present themselves for examination by the Board will make application to the Secretary of War, before September 1, 1897, for the necessary invitation, giving the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from which they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal acquaintance, from at least two reputable persons, as to his citizenship, character, and habits. The candidate must be between twenty-two and twenty-nine years of age, and a graduate from a Regular Medical College, as evidence of which, his Diploma must be submitted to the Board.

Successful candidates at the coming examination will be given a course of instruction at the next session of the Army Medical School, beginning November 1, 1897.

Further information regarding the examinations may be obtained by addressing George M. Sternberg, Surgeon-General U. S. Army, Washington, D. C.

A NEW DISPENSARY ABUSE.

A REPORT comes to us as we are about to go to press (as the *County Weekly* puts it), to the effect that a physician has been dismissed from one of the most fashionable dispensaries in a neighboring city (of course it could not occur in New York) for abstracting a fifty-dollar banknote from the purse of a patient.

The pocketbook was left upon the dispensary desk,

it is said, while the lady entered an adjoining room to prepare for examination. The plea made to the governing board by the physician was that he had been overworked, having treated over four hundred patients at the dispensary during the three days preceding the temptation which caused his fall, and that during this time he had been unable to procure but one full meal. Hunger, and the means at hand to appease it, may have proven too strong a combination for his overwrought nerves, but this naturally did not weigh with the board. The *clientèle* of the institution must be made to feel that while a patron is undergoing treatment his valuables are safe. The argument was used by one of the governors that, if the patients' money is to be taken from them, they might as well go to a physician's office and be done with it.

The crime of robbing a dispensary patient cannot be too severely punished, since such acts would soon deter many persons of wealth from patronizing these institutions. It is therefore most fitting that the culprit in the present instance will be forced to take his chances for the future in private practice.

There is something to be said upon the other side. It seems unwise for applicants to carry with them and display at the dispensary large sums of money, diamonds, and the like. It would surely seem to be in the nature of contributory negligence if in the future applicants for free treatment put temptation in the way of doctors, who after all are only human and often hungry. — *Medical Record*.

Obituary.

SURGEON W. H. H. HUTTON, U. S. M. H. S.

SURGEON-GENERAL WALTER WYMAN, of the United States Marine-Hospital Service, announces the death of Surgeon William Henry Harrison Hutton, of that service, June 14th, at the age of fifty-nine. After serving with distinction, as a volunteer, during the late Civil War, he was appointed assistant surgeon in the Marine-Hospital Service May 8, 1875, and was promoted to the grade of surgeon October 20, 1876. Surgeon Hutton, during his connection with the Marine-Hospital Service, served as commanding officer at the following stations: New York, Cincinnati, New Orleans, Detroit, Louisville, Mobile and Baltimore.

In addition to the above duties he rendered valuable service at Brunswick and Way Cross, Ga., and Camp Perry, Fla., in 1888, in enforcing the quarantine and other measures during the yellow fever epidemic of that year, and again at Brunswick, Ga., during the yellow fever epidemic in 1893. At Camp Perry he installed and was in command of the first detention camp which proved so successful in the management of the epidemic at that time raging in Jacksonville.

He was also placed in charge of the quarantine establishment at Sandy Hook, N. J., during the cholera scare in 1892, and later, in the same year, rendered efficient services in the establishment of the quarantine flotilla at Cape Charles. In 1894 he was detailed to inspect the quarantine stations along the Florida coast, and had temporary charge of the Gulf Quarantine during a part of the same year. For thirty-five years Surgeon Hutton has been serving his country in various capacities in war and pestilence, and always with a conscientious devotion to its interests, and with a zeal worthy of emulation. He was ever ready to obey a summons to duty, and oftentimes was a volunteer when epidemics threatened the country.

In his death the service loses one of its oldest and most efficient officers.

Correspondence.

IN NEISSER'S HOSPITAL.

BRESLAU, June, 1897.

MR. EDITOR:—Professor Neisser's hospital has already been described in your columns by Dr. Charles J. White; and it was through the kindness of his father, Prof. James C. White, that I was enabled to avail myself of its many opportunities. Before coming here, I wondered why the Munich men called Neisser the first teacher in Europe, and why even the Viennese, basking in the sunshine of the great Kaposi's presence, considered him a first-class man. I wonder no longer. It is because of the charming personality of the man. Without underrating his broad attainments and his powers of original research, he owes much of his success in teaching to his ability to interest while he instructs. It is worth one's while to see him in the clinic, surrounded by his students, asking this one to define some particular lesion on a patient's skin, another to observe the localization, then the size, the distribution, the symmetry; until, the puzzle having been put together, bit by bit, the diagnosis rises spontaneously and unconsciously to each one's lips. The teaching is done with all possible accessories. Photographs of chronic cases are taken from time to time, so that improvement or deterioration may be easily seen; wax models are made, and microscopic preparations are shown.

Treatment here embraces all sorts of agents, from the simplest forms of local application to electric baths and the Röntgen rays. To detail them would take too much time and space, and would not, perhaps, be particularly interesting except to the specialist. I think, however, that two diseases, namely, syphilis and gonorrhea, are of sufficient interest to all to warrant a description of the methods employed in this hospital for their relief. In attempting to briefly outline these methods, I shall supplement my own personal observations by quoting freely from one of Professor Neisser's recent articles, and also from late publications of his first assistant, Dr. Schaffer, taking only those points which seem to me important for our purposes.

Professor Neisser not only believes that mercury is the sheet-anchor in the treatment of syphilis, but also that it is the *only* specific. Other agents exist which are good adjuvants; but nothing which has any direct influence on the micro-organisms of the disease. Of the adjuvants, he naturally places the iodides in the first rank, but never accords them a higher place. He allows that in the later ulcerative manifestations, the iodides may cause the rapid disappearance of the apparent lesions, but contends that they never prevent their reappearance. Only mercury can do this. He uses iodide in the early period of the disease, if there be any severe pain, in the tertiary period, and in any stage of "malignant syphilis" in which it may be indicated. The dose rarely exceeds one gramme three times daily. Baths are also considered most important adjuvants. Daily baths not only favorably influence the specific work of the mercury already taken into the body, but also help elimination after the work is done, thus preventing intoxication. Private patients should, if possible, be sent to one of the many bath resorts for several reasons. In the first place, on account of freedom from business and domestic care, then on account of the necessarily regular habits of life, and finally, because of the good to be obtained from the daily bathing. The last reason is by far the most important. As that is, of course, impracticable for poor hospital patients, a substitute is offered them. It is found that sulphur and salt baths are perhaps the most efficacious. Therefore, what is called a "Vlemineckx's bath" is prepared; 150 grammes of Vlemineckx's solution is poured into an ordinary bath-tub, partially filled with water as hot as can be comfortably borne. Care should be taken that the tub be not of metal. When the patient is strong enough to bear it, he is allowed to remain in this bath from thirty minutes to an hour. This is given every other day. On the alternate day, hot air is introduced under the bed-clothes for about one half-hour, and the patient remains an

equal length of time tightly covered. When innunctions are used, however, these baths must be omitted, since the daily washing, rubbing and drying would remove from the skin many particles of mercury which ought to be, and which eventually would be, absorbed. Besides, the sulphur would be apt to combine with the surface mercury and form an insoluble salt which could not penetrate into the system. During the progress of innunction, therefore, an ordinary bath only is enjoined once a week.

The mercury is used, when possible, by intra-muscular injection. A Pravaz syringe is used, and the following formulas are principally employed:

R	Calomel	5 gm.
	Alapurin	10
	Liq. Paraffin	35 M.
R	Hg. Thymol	5
	Alapurin	10
	Liq. Paraffin	35 M.
R	Hg. Salicyl	5
	Alapurin	10
	Liq. Paraffin	35 M.

When the alapurin is not used, the proportions of the calomel, hg. thymol or hg. salicyl, would be 3 to 27 of liquid paraffin. The injection is given every four or five days, according to circumstances. The gluteal region is the preferable site. This has been long thought among us a decidedly uncomfortable place to have an abscess, and especially so at meal times, but with proper precautions the danger is not great. At any rate, I have never seen such a complication. The calomel injection is the quickest and most efficacious, but the hardest to bear. Therefore, ordinarily, it is given in one out of every three injections, and the other salts are used the other two times. A five-percent. solution of corrosive sublimate and table salt in distilled water is also used, but, like the calomel, is found somewhat hard to bear. When the injection is not considered proper, or when, as in the polyclinic, the patient is not able to receive it at the stated times, innunction is generally prescribed. It is to be used as follows: first day, on the right arm; second, the left arm; third, the right leg; fourth, the left leg; fifth, the trunk; and on the sixth, suspend treatment entirely, and thoroughly bathe the whole body, scrubbing vigorously with soap, so that the skin may be well prepared to meet the new innunctions which are to be recommended on the seventh day.

The chronic intermittent treatment is used, and every patient should receive six or eight courses in the first three or four years of the disease. These courses consist of energetic and weak treatments with periods of intermission. The energetic treatments last about forty days; the weak ones, about three or four weeks. Neisser contends that each patient should receive one energetic course in each year. During the periods of intermission, the body should be kept in the best possible condition. Naturally, these rules must be amended to meet the individual case. Each patient receives a printed card, giving directions as to care in living (especially useful for out-patients), the precautions that he should take as to public drinking-glasses, towels, etc., as to the cleansing of his teeth (which should be done three times daily with a soft toothbrush, and without wounding the gums), and as to the avoidance of marriage during the first three or four years of the disease, and then only after consulting a physician. He is assured, however, that if he faithfully follows the directions given, he may eventually marry without danger to either wife or children. He is also especially directed that, if he have any other illness, no matter what its nature may be, it is his duty to show the card to his attending physician.

Internal treatment is never (or, at least, I have never seen it) given in the hospital. It is, however, considered in Neisser's articles. In internal treatment, full courses of baths are indicated fully as much as in the handling by injections. In the treatment of private patients, there is no choice as to which of the many bathing resorts they should be sent. Care only is taken, in uncomplicated cases, that there be a competent physician residing in the place. When there is, however, a complication, such as diabetes,

nephritis, or malaria, such resort should be chosen as is best suited for the complicating disease.

Constant search is being made here, clinically, chemically and bacteriologically, for the perfect remedy for gonorrhea, but thus far without full success. A remedy to be effectual in this disease should possess the following properties: (1) It should be able, in proper solutions, to penetrate to the deeper layers of the mucosa, and yet not too strongly irritate and wound the membrane. (2) It should destroy the gonococci. (3) It should not enter into chemical combination with albumin or the mucin bodies, and thus lose its bactericidal properties.

The medicaments which best meet these requirements are, first, the silver salts (argentomin, argonin, argentum nitricum, actrol, itrol); and next hydrag. oxycyanatum and ichtiyol. Argosol is purposely omitted from this list, because it is yet *sub judice*. It is the latest of all the silver salts, and is being tried in the wards and experimented with in the laboratory. So far, it promises exceedingly well. Permanganate of potassium is not used, because it is considered too astringent. Neither are the ordinary astringent media, such as alum, copper and zinc. It is believed that astringents do not penetrate into the deeper layers; that they close up the mouths of the glands and imprison the burrowing gonococci, which should be destroyed and washed out. According to this theory, the copious irrigations of a solution of permanganate of potassium, so frequently used in the anterior urethra, would be of little avail.

Of the silver salts, argonin is the least irritating, but the least penetrating, and is ordinarily used in anterior urethritis, by the patient himself, in a solution of about $\frac{1}{3}$ to 200. Argentomin is the next in strength, and is employed for irrigations of the posterior urethra in solution of 1 to 4,000. Argentum nitricum also for the posterior urethra, in solution of 1 to 3,000-4,000. These three salts are the ones principally employed, together with the hydrag. oxycyanatum 1 to 4,000-6,000. Icthiyol is often used in strength of one to five per cent. Modifications of the treatment are necessarily being constantly made. Frequently the irrigations are suspended, for instance, and an instillation is made into the posterior urethra with an Ultzmann's catheter, or a Guyon. In these cases, the strength is increased, as for example, argentum nitricum, one to two per cent., may be used with good effect. Pencils or suppositories may also be considered of benefit. As a rule, argonin, being the least irritating, is the medicament preferred for a new and yet untried patient.

The same reagents are used in the gonorrhea of women, but in a slightly different manner from that to which we are accustomed. The urethra and the cervical canal only are treated. The vagina is kept clean, of course; but it is found that the vaginal pavement epithelium of women of experience offers little chance for the burrowing of gonococci. In the vaginae of children and young maids, however, the membrane is more tender, the epithelium is more generally cylindrical, and there is, therefore, greater necessity for careful and constant treatment. In ordinary gonorrheas of mature women, the urethra is carefully treated throughout its whole length with argentum nitricum, one to two per cent., as a rule, and then, perhaps, a pencil of ichtiyol is introduced. This is done, preferably, with an Ultzmann's catheter, and the cervix is treated with a Guyon. The vagina is thoroughly washed every day with clean, warm water. Neisser lays especial stress on the fact that we should never rely upon subjective symptoms as to the cure of a gonorrhea in women. Before being satisfied to suspend treatment, we should examine for gonococci; first, the urethra, then the meatus, next, any openings, inlets or folds about the urethral orifice, then the cervical canal, and finally any other inlets or outlets, especially noticing the secretion from the glands of Bartholini. He thinks that, if this were done properly and thoroughly, not only in every known, but in every suspected case, there would be fewer ascending gonococci, and much less after-suffering from infected tubes and ovaries.

Twice a week thorough examinations for gonococci are

made. The male urethrae are first gently stripped, and the resulting secretion is transferred to a clean slide. Next, a soft catheter is carefully inserted as far as the compressor urethrae, and the anterior urethra is washed out with a three-per-cent. solution of boric acid. The first part of the returning fluid is caught in a glass receiver, and any flocculent bits are placed on another slide by means of a platinum needle. When the anterior urethra is thoroughly cleansed, so that the fluid returns clear, the patient is instructed to pass his urine into another glass, and flocculent bits are again removed, as representing the secretion of the posterior urethra. If there be any suspicion of prostatic involvement, the gland is massaged through the rectum, and the resulting secretion collected. The various slides are marked, and afterward examined in the laboratory. The records of these examinations are as carefully kept as the temperature and pulse charts. If gonococci are not found, the patient is kept for a week without treatment, and then given an injection of nitrate of silver, and if there be no resulting micro-organisms, he is considered cured. The routine examination of women is of the secretion of the urethra, and the cervical canal. If, however, no gonococci are found in these places, then careful search is made of the parts before enumerated.

In this description I have omitted much, especially of the care of complications, and I fear that in other parts I have detailed even to the point of tediousness. I have been minute in describing some things, however, because they are not the ideas of a mere visionary theorist. On the contrary, they are the result of much patient investigation and much careful research on the part of a man, who was not only the original discoverer of the germ of gonorrhea, but who has been, perhaps, the first in the world in its scientific exposition.

While here, I have been much impressed with the thought of how much good such a hospital can do. I am not going to shock my good Puritan friends by suggesting a hospital for gonorrhea in Boston; but I see no reason why there should not be at least a ward for skin diseases and syphilis. Every other organ has its particular ward or its particular hospital. Why not the skin? It is surely as necessary to the general economy as any other essential organ of the body, and the results of its mal-treatment or neglect are generally far more noticeable. Many of the dermatoses are just as disabling and just as incapacitating from labor, as either pneumonia or typhoid, although, perhaps, not so prostrating. Many others are in fully as great need of careful, intelligent and frequent dressing as any of the surgical lesions. Why then, in our general charities, should we discriminate against dermatological patients?

Unquestionably, from a medical standpoint, cases of syphilis should be supervised by our local health authorities. At certain stages, the public welfare as imperatively demands the isolation of the patient as in any other of the communicable diseases. The instances of its innocent contraction are so numerous that one, nowadays, hardly records them. Such supervision and such sequestration are, however, impracticable in our present social conditions. But while a compulsory retirement cannot be enforced, it certainly seems senseless to practically forbid a voluntary one. We would not refuse hospital treatment to wounds received in a drunken quarrel. Why then be so relentless toward the victims of another and far more tempting encounter? Surely the one is not more disgraceful than the other. I am well aware that syphilis is treated in our almshouses; but almshouses are not hospitals, and neither should patients be compelled to become paupers. A female patient may, perhaps, find a haven in one of our numerous gynecological hospitals, but to the man no such opportunity is afforded. Let us hope that when the coming woman assumes the reins of government, she may, with an eye single to the interests of the coming babe, consider that man's sexual organs are as necessary to the great scheme of existence as her own, and that upon the healthful preservation of both depends the health of future peoples.

Yours very truly,

WM. G. MACDONALD, M.D.

Lecture.

PERFORATING WOUNDS OF THE EYE.¹

BY FREDERICK E. CHENEY, M.D.,

Assistant in Ophthalmology, Harvard Medical School; One of the Surgeons to the Massachusetts Charitable Eye and Ear Infirmary; One of the Ophthalmic Surgeons to the Out-Patient Department of the Massachusetts General Hospital.

I HAVE chosen the subject of "Perforating Wounds of the Eye," for this lecture, for the reason that it is a thoroughly practical one, and a practical knowledge of the special branches of medicine is what is most needed and desired, it seems to me, by the members of the general medical profession.

Perforating wounds, which are characterized by a perforation through the outer coat of the eye into its interior, must always be regarded as serious. In the first place, an object perforating the cornea or sclera rarely stops there, it goes deeper and usually results in a greater or less defect of sight; again, the object may carry septic material, or at least leave an opening through which micro-organisms may enter, and we have a second danger, that of septic infection; and, then, we have a third danger which is of still greater gravity, the danger of a sympathetic inflammation of the other eye.

Ocular injuries are, as a rule, emergency cases, and the larger proportion of them are first seen by the man in general practice. If he lives in, or near a city, he can if he chooses transfer the responsibility of the case to the oculist. If he is at a distance, it is necessary that something be done; and the future welfare of the eye often rests upon his ability to recognize the nature and gravity of the lesion and to prescribe appropriate treatment.

If a patient gives a history of an injury from some sharp instrument, like a pointed stick, scissors or needle, or from a flying bit of stone, steel, or other metal, the nature of the injury is at once suggested, and we look for the point of perforation. It is important to determine, first, the situation of the wound. A perforation through the ciliary region is to be regarded as the most serious, for the reason that the ciliary body is in all probability involved, and there is consequently a much greater danger of sympathetic trouble in the other eye than in wounds confined to the cornea, or to the sclera posterior to this region. It is also extremely important to determine whether or not the perforating object has remained in the globe. The fact that a foreign body is lodged in the interior of an eye adds greatly to the gravity of the situation. Even though it is very minute, has not entered through the ciliary region, and does not result in a marked defect of vision, a favorable prognosis cannot be given for the injured eye; and, unless the foreign body can be removed, there is again the added danger of sympathetic inflammation of the second eye. The nature of the perforating object will frequently assist us in settling this question. If it is a sharp instrument and not liable to break, there is little possibility of a fragment's being left in the globe, and we can usually decide the matter definitely by an examination of the object and seeing if there is any part of it missing. If, on the other hand, the injury is from an explosion, the breaking of a bottle, a lamp chimney, or something of that kind, it may be impossible to determine which piece caused

the perforation, or even to know its size. Our conclusions must then be drawn entirely from the condition of the eye; and the question unfortunately is not always definitely settled until we have removed the eye and opened it. Among the stone and metal workers there is often the history of a sudden blow from a small object, while sharpening tools or chipping stone; and if we can convince ourselves that there has been a perforation of the cornea or the sclera, we can feel fairly positive that the object is lodged in the interior of the globe. The patient may bring, as he frequently does, a bit of stone or metal which he is very sure "fell out" after it had struck the eye, but flying particles, having a sufficient force to cut through the cornea or sclera, rarely stop until they have gone considerably deeper, and, of course, cannot fall out again.

The question of infection by the perforating agent is also an important one to consider. In certain cases we can feel fairly confident that the object was free from septic material, and if suppuration begins that infection took place after the injury. In other cases, the chances are all in favor of septic material having been carried into the eye, and we should give a graver prognosis and adopt a more vigorous line of treatment. In locating a foreign body in the globe it is, of course, an advantage if we can know from which direction it came, and the patient can often inform us on this point with a considerable degree of accuracy. Having determined the foregoing points to the best of our ability, the eye should be systematically examined in order to find out to what extent the intra-ocular tissues have been involved. Before doing this it is best to make the eye anesthetic by instilling a two- or four-per-cent. solution of cocaine, and also to guard against septic infection during the examination; in fact, precautions in this latter direction cannot begin too early. The eye should be washed with a 1-5,000 corrosive-sublimate solution, the lids and adjacent tissues should be thoroughly cleaned, the examiner should look carefully after his own hands, and the dirty handkerchief which the patient invariably carries and mops the eye with at frequent intervals should be removed.

For convenience of description, perforating wounds may be divided into three groups: (1) those confined entirely to the cornea, (2) those involving the ciliary region, and (3) those in the sclera behind the ciliary region. When an object passes through the cornea, the tissues that are most liable to suffer injury are, of course, those situated just behind it, the iris and lens. In exceptional cases they escape completely, the object passing through the cornea into the anterior chamber, but not going deep enough to involve them in the least. Even then, if the perforation is not central, there is a chance of the iris being secondarily involved; for, if the anterior chamber is evacuated, as it usually is, the iris rests in contact with the corneal wound and may become firmly adherent to it. Also, if the perforation is of sufficient size we may have a prolapse, the iris being forced through the wound by the pressure behind it, and projecting beyond the corneal surface. It is exceptional, however, for the iris and lens both to escape when the cornea is perforated. It is not unusual to find the iris tissues extensively torn and lacerated, blood in the anterior chamber, the lens more or less opaque or even dislocated, and the sight reduced to a perception of light, and even this may be faulty in certain directions. Such extensive changes are not, of course, difficult to make

¹ An evening lecture delivered in the Graduates' Course of the Harvard Medical School, April 25, 1897.

out. When, however, the perforating agent is smaller, a bit of flying steel, for example, the extent of the injury may be overlooked unless considerable care is taken in the examination. At times, the corneal wound is so small that it is only made out when light is focused upon it by a strong convex lens, and may have closed so quickly that the anterior chamber is not evacuated. In this class of cases we occasionally see a little black point on the iris, in the neighborhood of the corneal wound, that suggests, in appearance, a foreign body lodged on its surface. Such a diagnosis should never be made, however, until the light has been thrown into the eye with the ophthalmoscopic mirror. Then you will probably find that what looked like a foreign body on the iris is really a perforation through it—it appearing black just as the pupil appears black by focal illumination, but giving a red reflex from the fundus by reflected light. This result will, of course, not be obtained if there is a very extensive opacity of the crystalline lens. After the pupil is dilated you are very apt to find a grayish opacity of the lens, and it is not uncommon to have this opacity take the form of a thin line extending backward from its anterior to its posterior surface. A foreign body may be found lodged in the lens; but if the grayish line of opacity extends entirely through the lens and if there is the history of a small flying particle striking the eye, it is reasonable to conclude that the foreign body has passed still deeper, and we must look for it in the vitreous, or even as far back as the retina or choroid. The vision may be nearly normal soon after the injury, and sometimes continue so for a very long period. A perforation of the lens, however, will usually result in a cataract; and blindness from this cause, from detachment of the retina or inflammatory changes, is to be expected sooner or later, if the foreign body remains in the globe.

A perforation through the ciliary region may be limited to that region, but more often it is a perforation involving the cornea as well. The wound is sometimes found extending entirely across the cornea into the ciliary region on one or both sides, and accompanied by such a general laceration of the intra-ocular tissues that it requires but little knowledge of ophthalmology to determine that the eye is hopelessly lost. A wound of the sclera does not stand out as clearly as one in the cornea, for the reason that it is apt to be obscured by the congestion and swelling of the surrounding conjunctival tissues. For this reason great care must be taken in the examination of corneal wounds extending to the periphery, to make sure that they do not run into the ciliary region. A ciliary wound, if extensive, may be complicated by a protrusion of the ciliary body, iris, vitreous or even of the lens. When small the edges may come into almost immediate apposition, and light must be thrown into the eye before we can judge of the amount of intra-ocular injury. A laceration of the ciliary body will naturally result in more or less hemorrhage into the vitreous, and this will be most dense in the neighborhood of the wound. If the perforation does not involve the crystalline lens we may be able to make out this blood-clot after the pupil is dilated, even by focal illumination. With reflected light, the red reflex of the fundus will be indistinct over this area, or may be completely obscured. Sometimes you will find a fairly isolated clot of blood in the vitreous at some distance from the wound; and, if the injury was from

a flying bit of metal or stone, it is not improbable that the foreign body is situated in this clot, and that it can be made out as the hemorrhage is gradually absorbed. The pupillary border in these ciliary wounds will not infrequently be drawn toward the point of perforation. The vision may be fairly good, but more often it is considerably reduced or completely lost. In perforations of the sclera posterior to the ciliary region the tissues that naturally suffer are the choroid, retina and vitreous. A prolapse of these tissues is not infrequently met with, and the loss of vitreous is sometimes so considerable that the tension is greatly decreased and the eye-ball even collapsed. If, however, the wound is clean-cut and not of great size, the edges may come into almost perfect apposition and there be no protrusion of the intra-ocular tissues whatever. Ophthalmoscopically you may find the fundus completely obscured by an extensive hemorrhage into the vitreous chamber, or you may be able to make out the optic disc, the macula region; in fact, the only obscured portion may be in the neighborhood of the wound. Occasionally a case will be met with in which the wound is so slight, and vision so little interfered with, that we may doubt very much if the foreign body has really entered the eye, until we come across it during our ophthalmoscopic examination, suspended in the vitreous or imbedded in the retina or choroid. A careful examination with the ophthalmoscope must always be made therefore in cases giving a history of a bit of foreign substance striking the eye, even though the external signs of injury are slight or wanting. The vision, as in cases of perforation of the cornea and ciliary region, is often reduced to a perception of light or even to complete blindness. It may, however, be found practically normal, and sometimes continues so indefinitely.

It is a good plan in all perforating injuries to get some idea as to the amount of sight in both eyes, at the time of the first examination, and to make a record of it. The prognosis will, of course, be influenced by the amount of vision found in the injured eye, as will also, to a greater or less extent, the line of treatment adopted; aside from this, if recorded, it may prove of value in case of a medico-legal complication arising later. Many men in general practice now have hanging in their offices a cardboard of test-letters, which is found convenient in a great variety of cases. If, upon examination, the patient is found unable to distinguish even the largest letters at any distance from the eye, his ability to count fingers should be tested. If he cannot count fingers, then his ability to tell which way the shadow of the hand moves in front of the eye—failing this, his ability to distinguish between light and darkness. It is also important to know if he perceives light over the entire retinal surface, or if it is absent in certain directions. In making this test the room should be darkened and a dim artificial light placed at the side of the patient's head, and far enough back so that it will not enter the eye. Then, while he looks directly forward, the light is thrown into the eye with the ophthalmoscopic mirror from the sides, above and below, and he names or points out the direction from which it seems to come. If the light is made out quickly and accurately in all directions, we conclude, although vision is reduced to light perception, that the retina is still intact. On the other hand, if it is not detected when coming from some one or more directions, it is more than probable

that the retina has lost its function by detachment or some other change over that area, and the prognosis for sight, which may be bad enough any way, will be practically hopeless.

Inflammation, after a perforation of the cornea or ciliary region, is to be expected, although it does not invariably follow. If, however, the wound is in the sclera, posterior to the ciliary region, it is not unusual to find a complete absence of inflammatory symptoms. An inflammation may result simply from a contusion and laceration of the tissues, and be characterized by a serous or plastic exudation, or it may be caused by the entrance of infectious micro-organisms which are liable to give rise to a most rapid and destructive suppuration. To illustrate, a patient gives the history of an injury from some object like a bit of glass, which was probably sterile; upon examination, we find a perforation of the cornea four or five millimetres in length, which extends to its periphery. There is also a hole through the iris near its outer border, and the lens capsule is ruptured. Two or three days later, there is more or less pain in and around the eye; there is intolerance of light, lachrymation, well-marked circumcorneal injection, a contracted and sluggish pupil, and a few iritic adhesions. The iris is not much discolored, and there are no signs of suppuration; in fact, the symptoms are those of a simply plastic iritis, and it is not probable that sight will be lost as a result of inflammation, if the eye is properly treated. In another case, the perforating object is the point of a scissor-blade. We feel fairly confident that septic material has been carried into the eye and shall naturally be on the lookout for symptoms of suppuration.

The symptoms accompanying pus formation in the interior of an eye are variable as to intensity. Occasionally there is but little injection, no pain, photophobia or great discoloration of the iris, and the only thing which suggests suppurative process is a deposit of pus at the bottom of the anterior chamber. More often, however, if there is pus in the anterior chamber, the iris will be found swollen and greatly changed in color, the pupil contracted and perfectly immovable, and the aqueous hazy. This condition will probably be accompanied by intense injection, the conjunctiva perhaps forming a swollen, elevated ridge, that is, a chemosis, around the corneal border, and by severe supra-orbital pain. At another time, the iris may be only moderately inflamed, but when the light is thrown into the eye we find a hazy condition of the vitreous at some point, which, after a little assumes a yellowish tint, obscures the red reflex of the fundus more and more, and we conclude that pus is being poured out from a suppurating area in some part of the ciliary body or choroid. Suppuration may cease under appropriate treatment, and the exudation become gradually absorbed. It may, however, continue in spite of every thing that can be done, until the tissues of the eye are so extensively involved that sight is absolutely lost, and a shrunken, atrophied globe, which is worse than useless, may be prophesied for the future. A progressive suppuration may be slow and continue for a number of weeks, or it may be rapid, involving the entire globe within a few days after the injury, and give rise to the condition called pan-ophthalmitis. The symptoms of pan-ophthalmitis are very characteristic, and can hardly be mistaken for anything else. The lids become greatly swollen and reddened, the edema sometimes extending a considera-

ble distance from the eye, the globe is pressed forward, appears two or three times its normal size, and the ocular-conjunctiva is infiltrated and brawny. The cornea and anterior chamber may be cloudy, and present unmistakable signs of suppuration, or they may be fairly clear at first, so that we can look through the pupil, and get a yellowish reflex from the pus deposited in the vitreous. The globe feels hard to the touch, and there is no perception of light. Within seven to ten days from the beginning of the process we may expect the globe to perforate, most often near the sclero-corneal junction. With the escape of pus, the pain, which has been extreme, ceases, and the inflammatory symptoms gradually subside.

A sympathetic inflammation of the second eye is what is most to be dreaded in perforating wounds. If the wound is far back in the sclera, or if in the cornea without extensive incarceration of the iris, the probabilities of such a misfortune are not great. If, however, it is in the ciliary region, if there is extensive incarceration of the iris in a corneal wound or, if a foreign body is lodged in the globe, it is an occasion for much anxiety. When there is complete blindness, we can quickly relieve this anxiety if we like, by removing the injured eye. In many cases, however, the eye is not blind, or injured in such a way that it will be unsightly, and we do not feel justified in advising immediate enucleation. The inflammation may subside after a time, a useful amount of vision be retained, and the patient go through life without further trouble. On the other hand, we may examine the patient one day, and the second eye looks perfectly well in every respect—a day or two later, there is complaint of a blur, or possibly only a feeling of irritation. We examine the eye again, and find a slight circumcorneal injection, a contracted pupil with perhaps one or two adhesions, and a few small lymph deposits on the posterior surface of the cornea. We now have a sympathetic inflammation, and the probabilities are that the second eye will become blind in spite of the most skilful treatment. There can be nothing more depressing than the memory of such a case, which might have been prevented if the injured eye had been removed a few days earlier. Sympathetic inflammation is most apt to occur from the third to the eighth week after the injury; it may make its appearance much earlier; and it is sometimes delayed for years. In fact, there is not absolute freedom from this danger as long as the injured eye is retained. Too often, there are no premonitory symptoms to indicate that the second eye is about to become involved. We shall, of course, expect to find the injured eye inflamed at the time of the sympathetic outbreak, and the inflammation involving the ciliary body and iris. This inflammation is not necessarily of great severity, however; and I have seen at least two cases where the patients gave no history of redness, pain or other signs of inflammation in the injured eye at the time, or for some time preceding the development of trouble in the second eye. Such cases are, of course, exceptional. Tenderness on pressure in the injured eye is usually present, but it may be entirely absent. It is a symptom which should always be carefully looked for; and its presence in an eye that is blind, or is fast becoming so, may lead us to decide that immediate enucleation is advisable. The second eye may show signs of what is called sympathetic irritation, that is, it tires easily, there is more or less photophobia and lachrymation,

the pupil is contracted, and perhaps also there is a diminished range of accommodation. Sympathetic irritation may be absent entirely, however, the eye appear perfectly well until it suddenly becomes inflamed; on the other hand, it is present in a large number of cases that never develop sympathetic inflammation. As a premonitory symptom, therefore, it is not of the greatest value although its presence will always cause more or less uneasiness.

The nature of this trouble, that is, sympathetic inflammation, has not as yet been definitely settled. There is little doubt, however, of its resulting from infection, and the sheath of the optic nerve is the most probable route of the micro-organisms from the injured to the sympathizing eye. The disease usually makes its appearance in the second eye, as an iridocyclitis, though it has occasionally been noticed that the optic nerve was first involved. As already said, the inflammatory symptoms in the beginning are frequently of an extremely mild character. Pain may be entirely absent, the ciliary injection may be very slight, and the sand-like lymph deposits, which are found on the posterior surface of the cornea may be the only suggestion of serious trouble. These lymph deposits should be carefully looked for in suspicious cases, and will usually stand out clearly against the red background of the fundus with a +7 dioptric lens behind the ophthalmoscopic mirror, if the observer is within two or three inches of the patient's eye. After a little we shall have the more characteristic symptoms of iritis, the well-marked circum-corneal injection, the supra-orbital pain, the discolored iris and the contracted pupil, with the formation of posterior synechæ. Sight may be destroyed within a few weeks, but more often the process is gradual. Sometimes under vigorous treatment the inflammation comes to a standstill; redness almost entirely disappears; there is little photophobia or lachrymation; and though there is some exudation and numerous iritic adhesions, the patient still retains useful vision, and we are encouraged to think that the process has come to an end. It is usually a false hope, however. The eye again becomes injected; the pupil gets smaller; there is more exudation into the anterior chamber and vitreous; the iris becomes adherent to the lens, not only at its pupillary border, but even at its periphery; the vitreous degenerates; the tension of the globe decreases; and we have in the end a blind eye, or more likely, two blind eyes, with little if any chance of restoring sight to either of them. Such a possibility, which may be called the tragedy of ophthalmic practice, has to be constantly borne in mind in the treatment of certain perforating injuries to the eye.

Now, in regard to the treatment of perforating wounds. There is one condition, if present, that should be attended to at once, and that is a prolapse of the iris. If the case is seen two or three hours after the injury, it may be possible to reduce it by instilling a one-half-per-cent. solution of sulphate of eserine or, if this is not easily obtained, a two-per-cent. solution of nitrate of pilocarpine. Its reduction can, of course, be attempted later than this, although if it does not return to the anterior chamber after three or four instillations of the myotic at intervals of ten minutes, the chances are that it will not, and it is better to abscise the iris tissue as near the corneal surface as possible. An abscission of the iris should not be attempted, however, unless one has the proper in-

struments, a spring speculum, a pair of delicate forceps, and narrow-bladed scissors, either straight or curved. If it is not done properly there is danger of doing more harm than good in attempting it. The eye is to be thoroughly cocaineized, and great care must be taken to avoid traction on the prolapsed iris when grasping it with the forceps, as there is the danger of drawing out still more of the tissue. If the wound is in the sclera, and there is a prolapse of the ciliary body, choroid, or vitreous, no attempt should be made at reduction. In case of a prolapse of the ciliary body, the safest treatment, it seems to me, is immediate abscission. There is, of course, the possibility of the vitreous escaping, but this chance should hardly count against the practical surety of an incarceration of the tissue if it is not abscised. In a prolapse of the choroid and vitreous body immediate abscission is often desirable, in order that the edges of the wound may come quickly into good apposition, a moderate incarceration of the choroid, however, is not liable to give rise to any very serious results. If a wound in the sclera is small, it can be left alone or covered over with conjunctiva. If it is large, and especially if the flaps do not come into good apposition, it is safer to unite them with two or three fine sutures.

The early use of atropine is something which should never be neglected in injuries where the iris is liable to become inflamed; in fact, it is a pretty safe routine treatment in all injury cases, and it is only very exceptionally that any harm will result. In case of prolapse of the iris, where a myotic has been used, it is especially important to instill atropine as soon as the anterior chamber is re-established. The reason why atropine is so necessary in these injury cases is readily understood. If we have iritis we get adhesions; if we dilate the pupil at once, and are able to keep it so, we avoid them and get rid of one source of trouble for the future. Cases where this precaution has been neglected are frequently seen by the oculist, the patient presenting himself three or four days after the injury, with a pupil firmly adherent to the lens, and possibly also exudation into the pupillary area.

The precautions and treatment mentioned are not always necessary, for the reason, that in certain cases, the best treatment is immediate enucleation. Delay means pain, loss of time—which is to be considered in the case of a laboring man with a family to support—and, perhaps, blindness in the other eye. Immediate enucleation is the best course to adopt, (1) in cases where the injury is so extensive that there is no chance of restoring vision, and little probability of an eye that will look as well as an artificial one; (2) where the wound is in the ciliary region, and the sight is lost, even though the chances are in favor of the patient's recovering with a presentable eye; and (3) where vision is lost, a foreign body is lodged in the globe, and there is little possibility of its being removed. Of course, there are other conditions where it is probable that enucleation will be the best course to pursue, but there is some doubt, and we give the eye the benefit of the doubt for a few days, and wait developments. When there is no question in the mind of the physician that the eye should come out, its removal is to be advised and performed as soon as the patient's consent can be obtained. A delay of two or three days so soon after the injury will probably make no difference whatever; but a want of decision on the part of the physician, and a postponement from day to day,

will often result in the patient's taking a decided stand against an operation which he would have accepted without question if the case had been clearly and forcibly stated to him in the beginning. That the practical surety of one good eye through life is better than the chances of two blind ones, is my final argument in such cases; and it is one that most patients are usually fully capable of comprehending.

If immediate enucleation is not demanded, an effort must be made to save vision, or at least an eye that will not be a source of danger to its fellow. The plan of treatment will, of course, vary considerably with the nature of the injury; it is to be remembered, however, that all perforating wounds are serious, and demand the most careful attention on the part of the physician. If a foreign body is lodged in the lens, in the vitreous or some portion of the fundus, we may have no immediate inflammatory reaction, and it is simply a question of deciding what is best to be done in regard to the foreign body. A foreign body in the lens need cause little worry as long as it remains there. The probabilities are, however, that after a time it will escape into the anterior or posterior chamber, and give rise to a severe inflammation and one that will endanger the other eye; for this reason, its removal should, as a rule, be attempted. The best chance is offered, it seems to me, by extracting the lens and the imbedded foreign body with it. If the case can be kept under observation, it is better to wait until the lens has become partially or completely opaque before attempting this, for the reason, that in a non-cataractous lens, the cortical is extremely sticky and does not escape readily from the anterior chamber. It is also best to have an electro-magnet on hand, if the foreign body is steel. A foreign body in the vitreous or imbedded in the retina or choroid, is always a source of much anxiety, especially if the patient has useful vision, as he frequently has. If it is a bit of steel, it is often best to attempt its immediate removal by means of the electro-magnet, even if vision is not greatly impaired. The chances of removal are fairly good, although the prognosis for sight must be extremely guarded. However, if the patient understands that sight will probably be lost sooner or later any way, and that the danger to the other eye is considerable, he will usually be willing to take his chances. If it is a bit of stone, or some other object, it can sometimes be grasped with small forceps entered through the wound, or through an incision made in the sclera, though such good fortune is exceptional. Where the foreign body is removed there will be little danger of sympathetic trouble if the ciliary body is not involved, and the patient can retain an eye that will probably look well and possibly have useful vision. If the attempt at removal is unsuccessful, and if the case is complicated by severe inflammation, the eye should be enucleated. If the eye is not inflamed immediate action is not always demanded, though the patient must be kept under constant observation. The extraction of a foreign body from the globe is something which would hardly be attempted by a man in general practice, and the prevention and treatment of the inflammatory complications which are liable to arise as a result of perforating wounds will fall more within his province.

As I have already said, if the perforation involves the iris or ciliary body, inflammation of a greater or less severity is to be expected, and every attempt must

be made to combat it by appropriate and vigorous treatment. In the first place, it is advisable that the patient be kept in bed for a few days at least, and that the room be moderately darkened. It is also a good plan to give a saline cathartic as early as possible. If the eye has been bandaged, the bandage is to be removed and should not be worn, as a rule, during the patient's confinement to the house. In old patients, especially, a bandage worn constantly is liable to give rise to catarrhal-conjunctivitis, not infrequently characterized by a copious muco-purulent discharge. The reason for this is, that a large proportion of people beyond middle life, have a mild chronic conjunctivitis, and it is impossible to use strong enough germicidal solutions in an eye to entirely free it from micro-organisms. Bandaging the eye raises the temperature, prevents the escape of secretions, and these conditions naturally favor the development of germs. This fact is often made prominent in cases of cataract extraction. The eye is washed thoroughly with a 1-5,000 corrosive-sublimate solution, the lids and surrounding tissues are carefully cleaned and all the ordinary precautions are taken to render the operation as aseptic as possible. In spite of this, a well-marked catarrhal conjunctivitis may develop, which gets worse from day to day, and only subsides after the bandage has been removed. If the patient is obliged to go out there will be less liability of infection if the eye is bandaged for a few hours than if it is left exposed; also, in cases where the lips of the wound do not come into good apposition, it may be the only course to adopt, but, until the external wound is healed, the chances of infection will be much greater in the majority of cases, with a bandage than without it. The eye should be washed ten or fifteen times a day with a saturated solution of boric acid, the lids and the surrounding tissues, as well as the patient's hands, are to be kept clean, and a cold boric-acid compress should be applied to the closed lids. The patient must, however, be encouraged to open the eye at intervals of ten or fifteen minutes, in order to prevent a retention of secretions. The cold compress is of value for the first few days as an agent in decreasing the tendency to inflammation; after the development of an iritis or cyclitis, however, it is better to use hot applications. Atropine or some other mydriatic is to be used from the beginning, and continued until the inflammation is at an end. A one-per-cent. solution, three or four times a day, will, as a rule, dilate the pupil and keep it dilated; but at times greater frequency or a stronger solution is necessary to accomplish this, and in the more violent cases we may find the pupil getting smaller and smaller from day to day, in spite of everything that can be done. A pupil contracting under atropine is always to be looked upon as an unfavorable symptom, as it denotes an increased congestion and infiltration of the iris tissue.

As just said, hot applications are advisable after an inflammation is well established; and we can make use of a hot boric-acid solution, applied as an absorbent-cotton compress, for twenty minutes to half an hour, every few hours, or we can use the popular camomile fomentations. Pain is often much benefited by heat, and, when severe, fomentations can be used very frequently. Leeches are not very generally used at the present time, but they are still frequently employed by the ophthalmic surgeon, and in diseases of the iris and ciliary body, especially, are of undoubted

value. In cases where severe inflammation seems probable, it is my custom to apply two or three leeches to the temple as soon as the patient can be put to bed, and to use one or more daily until the inflammation begins to subside. Severe pain will often cease almost entirely after the application of a leech, and their application in the early part of the evening may insure a good night's sleep to the patient. In cases, also, where the pupil grows smaller in spite of the instillation of atropine, it is surprising to see how quickly a leech will sometimes cause it to dilate. Careful watching is very important, and a daily visit advisable, until the inflammatory symptoms become decidedly less marked. The case may be said to progress favorably when pain becomes less severe and frequent, when the injection becomes less intense, and the other symptoms characterizing an inflammation of the tissues involved begin to subside. If these symptoms become more marked from day to day, if the eye develops tenderness in the ciliary region when pressure is made with the fingertips, if sight decreases, we become anxious, not only in regard to the injured eye, but for the other as well, and the question of enucleation is one which it may be necessary to decide at any time.

There is, naturally, a chance for much individuality of opinion in deciding for or against enucleation, as it is impossible to say, in a given case, just how much danger there is of sympathetic inflammation. Where most expected it may never develop, and it may make its appearance suddenly and without warning. It is the duty of the surgeon, it seems to me, to regard the eye only as an organ of vision in these doubtful cases, and when it ceases to fulfil its function to sacrifice it rather than take chances of blindness in the other eye. It is in cases where vision remains and symptoms develop, like extreme tenderness on pressure, sudden irritation of the other eye, etc., that it is difficult to decide what to advise; and, unfortunately, no general rule can be laid down for our guidance. If symptoms of inflammation develop, a blind eye is, of course, to be removed at once. If the exciting eye is not blind, and there is no strong probability of its quickly becoming so, it is better not to remove it, as it may be the more useful eye of the two in the end. In a case of pan-ophthalmitis, which may develop rapidly at any time if the eye has been infected, there is, of course, no question of saving the eye, and our aim should be to bring the suppuration to an end as soon as possible. When the symptoms are well enough established to leave no doubt as to the diagnosis, the eye may be incised with a small scalpel and then poulticed continually. Pain will usually cease in a few days, and after suppuration has subsided, the small, shrunken globe should be taken out. During pan-ophthalmitis there is fortunately little danger of sympathetic trouble, the reason possibly being that the lymph spaces are so completely closed by the swelling of the tissues that micro-organisms which give rise to the trouble, do not readily escape from the inflamed eye. Enucleation is practised by some surgeons during pan-ophthalmitis; and although the risk is not great, there have undoubtedly been cases of meningitis as a result, and it is just as well not to take chances.

I will close this lecture with just a word in regard to the treatment of sympathetic inflammation. Treatment should begin at once, and be carried on with the greatest perseverance. Atropine is to be instilled, leeches are to be applied, and the eye kept as free

from all irritation as possible. Complete darkness and rest in bed are desirable for the first few weeks at least. Mercurial inunctions are to be prescribed, and continued as long as the patient's condition will permit. The general health is, of course, liable to suffer more or less, and it may be necessary to modify the above treatment considerably.

CHRONIC ULCER OF THE STOMACH.

REPEATED HEMORRHAGE, EXCISION OF ULCER, DEATH.¹

BY ELBRIDGE G. CUTLER, M.D.,
Visiting Physician, Massachusetts General Hospital,

AND JOHN W. ELLIOT, M.D.,
Visiting Surgeon, Massachusetts General Hospital.

T. N., AGED forty-seven, married, born in London, England, living in Roxbury, Mass., a tailor by trade, entered the Massachusetts General Hospital July 24, 1895.

His father, three brothers and one uncle died of phthisis pulmonalis.

He was a moderate drinker of alcoholic beverages and used twelve cents' worth of tobacco per week. He had had no venereal disease.

He had measles, scarlet fever and whooping-cough in childhood. Five years ago he had acute articular rheumatism, with purpura, no dyspnea or palpitation accompanying it. Jaundice twenty-one years ago. For thirty years had been subject to morning cough. Sputum scanty; no blood. Had always been subject to attacks of digestive disturbance, often of an acute character of late years.

Present Trouble.—For the last two years has suffered from severe distress in the epigastric region, having paroxysms of sharp gripping pain which doubled him up, coming on at variable intervals after meals; sometimes within an hour, sometimes as late as five hours. Food seemed to relieve; was often relieved by belching. No vomiting until within three months. Worked up to three months ago. For the last three months fairly constant pain in the region above the navel, not relieved by food as before. Solid food gives increase of pain, but pain persists on starvation. Vomited occasionally, at first food and bile. For the last six weeks has vomited once daily; as a rule, at 3 A. M. or thereabouts, in large amount, and containing sometimes food taken thirty-six hours before. The vomitus consisted of partly-digested food till five days ago, when he suddenly vomited two quarts of thick brown liquid, and felt very weak and dizzy afterward. Since then has vomited daily a brownish stuff containing coffee-ground-like matter but no bright blood. Has lost thirty-five pounds in three months. His color has become very white. No jaundice. Eyesight good. Never uses lead in his work. No pains in the limbs. No trouble with the urine. His work entails constant pressure of tools on the stomach.

Examination.—Face extremely anemic; of a white, glistening pallor. Skin everywhere very dry and flaky. Face somewhat wasted; body much wasted, but not emaciated. Pupils equal, react to stimuli. Tongue clean. Mucous membranes anemic.

¹ Read before the Clinical Section of the Suffolk District Medical Society, February 17, 1897.

Heart apex in the fifth intercostal space in the normal line. Sounds feeble but clear. The lungs show a few fine moist râles at both bases behind. Abdomen is flat on the lower part, full over epigastrium and hypochondria. On inspiration epigastrium is bulged out by a rounded tumor tympanitic on percussion — apparently a distended stomach. Liver flatness begins at the eighth rib in the mammillary line and extends two inches below the costal border. Tenderness over the epigastrium general. A few small glands in the groin. Deep reflexes absent, superficial ones present.

Special analyses of the urine, blood, vomitus and stools, as follows:

Urine: Color pale, reaction acid, specific gravity 1.024. Albumin none, sugar none, bile none. Sediment scanty, and contains uric-acid crystals. Indican normal.

Blood: The red corpuscles numbered 2,100,000 in the cubic micro-millimeter; the white corpuscles, 12,000. Hemoglobin 35 per cent. The Ehrlich color analysis in 500 corpuscles gave polymorphonuclear neutrophils 73.8 per cent., lymphocytes 17.2 per cent., large mononuclear and transitional 7 per cent., eosinophiles 2 per cent., myelocytes 0. Many microcytes and macrocytes, few poikilocytes, one normoblast, no myeloblasts.

Patient allowed no food by the mouth, was given ice to suck and a nutrient enema every six hours consisting of peptonized milk three ounces, beef-juice two ounces, and one raw egg. He, nevertheless, vomited at 11 o'clock at night one quart of brown, tarry-looking matter, the consistency of porridge, containing no fresh blood. Vomitus contained free hydrochloric acid, a very small amount of lactic acid, hemin, no free blood, and very little food. Stools were light-colored, foul-smelling, and contained neither hemin nor blood.

For the next five days the patient was fed by nutrient enemata. There was no vomiting; but once or twice in the night there was pain in the stomach, which was relieved by chloroform-water. The nutrients were retained perfectly; and, as he complained of extreme prostration, two drachms of absolute alcohol had been added to each enema. The urine was thirty-five ounces in twenty-four hours.

July 29th. Stools contain no hemin. To-day two coddled eggs and one ounce of finely minced chicken were given for proteid diet at 12 M., to test the digestion leucocytosis. At 12 M. the white corpuscles were 7,650; at 4 P. M. the white corpuscles were 11,600; showing a digestion leucocytosis of 4,000.

The next day milk was given in small quantities at three-hour intervals, which gave no distress. The stomach was washed out after twenty-four hours' feeding, and much residue was obtained. The contents contained undigested food, lactic acid, no free hydrochloric acid, no blood. The stools that day (July 30th) contained some free blood. The white corpuscles, with constant feeding, continue at 11,000. Now on a diet of milk and lime-water, two ounces every two hours, alternating with albumin water, two ounces every two hours.

August 1st. Stomach wash. Very little food residue. Feels very comfortable. Stomach contents contain free hydrochloric acid, lactic acid, no blood. Stools liquid, hemin present. The food was omitted by mouth, and nutrient enemata every six hours were resumed again.

August 4th. Comfortable. No vomiting since first day. No blood in stools past three days. Sour belching at times; acidity relieved by bicarbonate of sodium, ten grains, p. r. n.

August 7th. Milk diet by mouth resumed.

August 8th. Vomited eight ounces of thick coffee-grounds at midnight, preceded by no pain or straining. The vomitus consisted of black, abnormally-changed blood. No hydrochloric acid. Lactic acid present. Food by mouth omitted again. Blood-count showed the reds at 2,450,000; whites, 6,000; hemoglobin, 38 per cent.

August 14th. As he was believed to have chronic gastric ulcer with recurrent hemorrhage, operative interference was then considered, and Dr. J. W. Elliot was asked to see him in consultation. He confirmed the diagnosis, but advised delay.

For the next six days he remained very comfortable, and was taken out into the open air daily in a box-bed.

August 21st. Blood: reds, 2,630,000; whites, 6,500; hemoglobin, 36 per cent. Strained soups were given.

August 23d. Mellin's food added.

August 24th. Gastric distress again. Looks and feels miserable.

August 26th. For two days has frequently regurgitated or vomited thin, sour, dark fluid (six or eight ounces in twenty-four hours), in which hemin crystals are found. No hydrochloric acid, a little lactic acid, some leucocytes. Omitted food by mouth. Urine normal.

As the patient was getting much weaker and was evidently bleeding continually, he was transferred to Dr. Elliot's service for operation. E. G. C.

OPERATION, BY J. W. ELLIOT.

When I first saw the case reported by Dr. Cutler, we agreed that an operation should be done. At that time the patient was doing pretty well. He had not had any vomiting of blood for several days; and I thought it would be wise to wait and see how much improvement he would make. But, as often happens when you wait for an improvement, we lost a good opportunity. He had another hemorrhage, which made him still more anemic, and he came to the surgical side in a very poor condition. As it turned out, it would have been better to have operated when I first saw him and Dr. Cutler gave me a good chance.

When he came to my ward, he was very white, pulse 100, temperature 100°. I operated as soon as I could. On opening the abdomen, the pyloric end was found to be a hard mass of cicatricial tissue nearly as thick as my wrist, and extending up on to the lesser curvature of the stomach. On incising the pylorus, the obstruction was found to be complete or nearly so. The cicatricial tissue in the stomach from the inner side was rough and friable, and in a very degenerated condition; and this extended over a large surface, so that the operation of leaving the disease and cauterizing it seemed to me out of the question. I therefore decided to excise the pylorus and all the diseased tissues, and take out about one-fifth of the stomach, including the whole of the lesser curvature on the anterior and posterior sides. The operation was not very difficult. There was no bleeding and everything went smoothly; but when I came to sew up the stomach, I found that in taking out the lesser curvature I had made a pointed

pylorus, that is, the part of the stomach remaining after the disease had been excised was long and narrow. To make a well-shaped stomach it would have been necessary to excise more than one-half of the stomach. However, I finished the operation, and the new pylorus was rather narrow, but still much wider than a stricture would be; you could put your finger through it easily. The man stood the operation without any shock, and seemed to be doing very well for two days. He was fed by nutrient enemata. On the third day he awoke in pain; the temperature went to 101°, and the pulse to 120. From that time on he sank and died. I opened the abdominal wound to see if the stitches had given away, and could find no evidence of anything wrong about the suture of the stomach. He died on the fourth day. At the autopsy no peritonitis was found, no leak from the stitches, but the stomach was full. He had not been allowed to take anything by the stomach, and why it should have been full I do not know. I do not know what he died of. He was in very poor condition, but he stood the operation well.²

In regard to the general subject of surgery of the stomach, it is to-day in a very interesting and promising condition. In 1879 Péan did the first operation of resection of the pylorus, with a fatal result. In 1881 Billroth began to operate, and had the first successful pylorotomy. In 1881 Woelfler invented the operation of gastro-enterostomy, which is anastomosis of the stomach with the intestine, intended also to relieve stricture of the pylorus. In 1882 Loretta brought forward his operation for dilating the narrow pylorus by opening the stomach and putting the finger or an instrument in and dilating. From 1881 to the present day great progress has been made and more and more cases have been reported. In 1895 or 1896 they were in large numbers and many of them successful.

As the matter stands now, there are for the relief of this difficulty eight operations to be considered: first, resection of the ulcer itself; second, resection of the pylorus; third, gastro-enterostomy; fourth, Loretta's operation; fifth, pyloroplasty, which consists in cutting the stricture lengthwise and sewing it up transversely; sixth, opening the stomach and cauterizing the ulcer; seventh, the combination of a resection of the pylorus and an anastomosis with the bowel; lastly, the closure of the perforated ulcer. From the very abundance of these inventions the surgeon, when he opens the abdomen and sees the condition of the stomach, either stricture or ulcer, has a very complex problem in his mind. All these operations have certain advantages and certain disadvantages in a given case, and they all have different mortalities; so to use them properly, one must keep in mind just what these mortalities are and apply the right operation for the special condition. As an example, take gastro-enterostomy, in which the mortality is lower than in pylorotomy; but in making an anastomosis you sidetrack a piece of intestine and food remains stagnant and makes irritation and trouble in that part. Moreover, although the mortality is less, the disease is not necessarily cured, especially if it happens to be malignant disease.

Now I take it that what this Section would like to

bear is just what can be done at the present day for the various conditions which in these cases, come up and what the chances of cure are: I will try to condense it, and shall not go into the details of operations. We will begin, first, with the perforated ulcer. The perforated ulcer, of course, is a desperate thing; the abdomen is filled with the contents of the stomach and acute peritonitis begins at once. One would naturally suppose that nothing could be done for this condition. I supposed the mortality would be 95 per cent. I had a case myself which died at once after sewing up a perforated ulcer and washing out the abdomen. As a matter of fact, in the last two years there have been six or seven cases which got well after washing out the abdomen and sewing up a perforated ulcer. The only statistics I could find is a collection of a small number of cases by Pariser—43 cases, with 10 cures, a mortality of not over 75 per cent., which to me is astonishing considering the probability of septic infection of the peritoneum. Perforations of the bowels, with extravasations of the feces, are almost invariably fatal; and the only way to explain the difference is that the contents of the stomach are not so infectious as the contents of the bowel.

Then the next thing to be considered is what are the chances for cutting out the ulcer before it has perforated, simply cutting out a V-shaped piece. The mortality of those operations up to date is 50 per cent.

Then pylorotomy, of course, is the great curative operation in these cases. Pylorotomy means cutting out the pyloric end of the stomach and sewing the duodenum to the stomach. This operation at first had a very high mortality. Billroth had a mortality of 60 per cent. It has gradually been reduced to about 40 per cent.; and Czerney, who is one of the best operators, has a mortality of 35 per cent., and Kocher in his last nine cases had only two deaths.

Gastro-enterostomy may be done for ulcer, this leaves the base of the ulcer to heal with lessened irritation from the intestinal contents. Its mortality is about 30 per cent.

Then Kocher has opened the stomach on account of ulcer, cauterized it, and made an intestinal anastomosis in order to carry the stream of digestive fluids past it, in two cases, with good results.

Next let us consider what can be done for stricture of the pylorus, the result of ulcer. The operations are pylorotomy, with a mortality of 35 per cent., gastro-enterostomy, mortality 30 per cent.; and Loretta's operation, which has a mortality of about 15 or 20 per cent. The mortality is lowest in Loretta's operation; yet the disease is not necessarily cured by this operation, and from what we know about strictures in other parts of the body, it seems very probable that after dilating a cicatricial pylorus the stricture may return. It has the danger also of possibly tearing the pylorus in dilating; and in that case it would be very awkward to mend, much worse than doing a resection at once.

Pyloroplasty is one of the best operations in suitable cases that can be done. It is founded on an idea which is involved in the modern treatment of strictures of the preter and various other organs. (Illustrated by drawing on blackboard.) If we have here the pylorus and here the strictured part, the cut is made down through the stricture so, then the cut is spread open so, and still more widely until the sides are brought together in this way. Starting with a cut, it is spread open until this side is sewed to that,

² Autopsy per wound. No signs of peritonitis. Stomach full of food; duodenum empty. No leak about the stitches. The temperature throughout stay at hospital was from 98° to 100° F. until August 24th, when it rose daily to 99.5° to 100.8°; 101°, 102°, 103°; died. Pulse between 80 and 90 till August 24th, when it rose daily till death.

making a straight line at right angles to the cut. Dr. Beach has recently done a case of that sort with great success. In a suitable case, where the stricture is small and movable, it is a very good operation, and the mortality is quite low. Corazza collected 53 cases, with only 6 fatal ones, 12 per cent.

The technique of these operations is now pretty well settled, and the mortality will not be much lower until the diagnosis is made quicker and the operation is done earlier. Early exploratory incisions would lead to many more cases. Of course, I have no idea that the majority of chronic ulcers of the stomach ought to be treated by operations. I understand from the literature that 85 per cent. of them get well, consequently I should not think of suggesting that an ordinary chronic ulcer be operated on if it is doing well. It seems to me there is no question in a case like Dr. Cutler's, a cicatricial stenosis of the pylorus with exhausting hemorrhages; I think that is a clear indication. One of the German authorities I happened to come across to-day suggests that an operation on an ulcer is indicated whenever any severe symptoms appear. I suppose he meant by that whenever it was doing badly in any particular way, when the pain became too severe, or when hemorrhages come on, or when the medication or washing out became inefficient. It is at present difficult to state exactly the indications. I should like to hear what some of the medical men think the indications are.

J. W. E.

So far as I know, Mikulicz³ was the first to operate for uncontrollable hemorrhage in gastric ulcer. It was in a patient being treated for constant hemorrhage from an ulcer of the pylorus. The ulcer was energetically cauterized with the thermo-cautery, and the narrowed pylorus was divided and sewed up, so that a new pylorus was formed (pyloroplasty). The patient died of collapse and circumscribed peritonitis three days after the operation.

Küster⁴ operated in a case of uncontrollable hemorrhage from a gastric ulcer with good result, by cauterizing with the Paquelin cautery the base of the ulcer which was adherent to the pancreas. He also did gastro-enterostomy because of an existing cicatricial stenosis of the pylorus. The hemorrhage stopped and the patient recovered.

Rydgier excised an ulcer of the stomach in which life was threatened from bleeding, successfully, as did also Billroth and Lauenstein with success. Kleef did the same operation, but without a favorable outcome.

Fleiner⁵ considers excision to be indicated in inveterate gastric ulcer where the conditions do not allow of an appropriate diet and proper care.

The two mistakes in this case of ours were in giving the diet by the mouth to obtain the digestion leucocytosis, which was unnecessary, the diagnosis being already established, and in the delay of the operation. I am convinced that if operation had been done earlier, before the patient had become so reduced, he would have stood a better chance to battle for his life.

A CASE OF ACONITE POISONING.¹

BY R. W. GREENLEAF, A.M., M.D., BOSTON.

ON January 11, 1897, Mr. C., fifty-two years of age, took by mistake for tr. rhei, between two and three drachms of tr. aconiti rad. He had mixed it with half an ounce of milk of magnesia in water. Burning of the fauces resulted immediately. His son, shortly afterwards, gave a mustard emetic. It not acting, he gave two doses of zinc sulphate, gr. xx each. The time, including procuring the emetics and free emesis, was about thirty minutes.

I was then sent for, but, being in attendance elsewhere, Dr. F. R. Tower kindly responded, arriving some ten minutes later. The chief symptoms then were, burning of the fauces; tingling of the lips, hands and feet; and restlessness. The pupils were slightly dilated. The pulse was 80 and of fair strength.

Tr. digitalis, m. xii, was given by the mouth, and at once rejected. A copious water enema, followed by one of brandy, oz. i, and tr. digitalis, m. xii, was next given. A half-hour later prostration came on, with labored breathing, weak pulse and sense of intense cold. Tr. digitalis, m. xii, and strychnine sulph., gr. $\frac{1}{20}$, were given subcutaneously. The foot of the bed was raised and heaters were applied.

The prostration being alarming, Dr. C. H. Underhill was called in consultation. Brandy was then given subcutaneously several times.

On my arrival, three hours from the ingestion of the poison, the condition was as follows: prostration marked; icy perspiration universal; respiration labored and variable, averaging 32, pulse at times not felt at all, when felt scarcely perceptible, slow and irregular; nausea and occasional vomiting of mucus; tingling of extremities and epigastric pain. Pupils reacted equally and were of normal size. Mentality clear. Remarkably calm, though apprehensive of impending death. Speaking required much effort.

Strychnia, gr. $\frac{1}{20}$, was again given subcutaneously. Brandy, oz. i, with equal parts of water by enema, and repeated twice in half-ounce doses. The condition continued precarious for another hour, with heart sounds irregular and scarcely audible. Atropine sulphate, gr. $\frac{1}{50}$, was then given hypodermically. This was followed by increased strength of the respiration and pulse and by drying of the skin. At this time the patient complained considerably of peripheral tingling and of intense burning pain in the epigastrium. As the vomiting had continued, we at first gave champagne, half an ounce, which was at once rejected. A sinapism was then applied to the epigastrium, and bismuth subnitrate, gr. x, given by the mouth and retained. This was repeated twice in hour intervals. Milk, in half-ounce doses, was given every half-hour.

The condition now, after five hours, gradually improved. In eight hours the pulse was of fair strength, regular and about 80 per minute. Respirations were about 28. In nine hours he began to complain of rectal tenesmus and to void small mucous and bloody stools. These symptoms persisted annoyingly some six hours, and finally yielded in three hours more, after rectal irrigation with warm water, a Rochelle powder by the mouth, half an ounce, and later ol. ricini, half an ounce, taken in capsules. As the urine had not been passed during the day, he was catheter-

¹ Read before the Clinical Section of the Suffolk District Medical Society, February 17, 1897.

ized fourteen hours after taking the poison. Six ounces of somewhat concentrated urine were collected.

From this time on no other treatment was given, save bismuth, gr. x, at intervals of six hours, and lime-water with milk.

On the following day he felt very weak, but the heart was acting well. The gastro-intestinal pain was quite severe, and all food but arrow-root, milk and ice-cream was avoided. He passed small quantities of urine from time to time, and also some mucus with the otherwise normal stools. For a week the epigastric burning and the tingling of the extremities continued, and then gradually wore away. The tingling was of a peculiar character, mapping out to the patient, as it were, successive areas. In this way he felt that he could localize the nethral orifice of the bladder and the cardiac orifice of the stomach. This sensation did not leave the anus till about the tenth day. Up to the fourth day the submaxillary glands were quite tender and painful. At the end of a week an ulcer, two inches in diameter, formed on the left scapula region, and two small ones on the hips, presumably from burus. The latter are healed, but the former still has a small granulating surface. The patient is outdoors daily, but full strength has not yet returned.

In comparing this case with others, its interest is found to lie in its rarity, the dangerous character of the drug, and the lessons to be learned for the treatment of possible future cases.

Aconite poisoning is exceedingly rare, considering that the drug is an ingredient of a common liniment and is almost a household word from its free use to-day. Enough cases are reported to make a sufficient basis for study. Woodman and Tidy in their edition of 1877, p. 354, report 33 cases and refer to eight others collected from medical journals and works on toxicology between 1807 to 1872. Dr. G. H. Tucker reports, in the *New York Journal of Medicine* for 1851, p. 222, 53 cases, similarly collected.

The alkaloids of the aconite plant are found in both leaves and root, but are strongest in the root, from which the present official preparations are derived. Aconite root has been mistaken for horse-radish root and caused fatal poisoning. Death has resulted from one drachm of the tincture on several occasions. Twenty-five minims in one case and twenty-five drops in another have resulted fatally. One-tenth of a grain of aconitia would prove fatal in a man, and one-fiftieth has produced alarming symptoms. On the other hand, recoveries have taken place after the ingestion of as large doses as one and a half ounces of the tincture. The acute symptoms appear in from a few minutes to an hour. Death usually results within three or four hours. In one case it occurred in twenty minutes. On the other hand, it has been delayed as much as twenty-four hours.

H. C. Wood and others report at length on the pharmacology of aconite. The effects of slowing the heart, of embarrassing respiration, of rendering peripheral nerves anesthetic, and of chilling of the body without affecting cerebration are ascertained. The exact way in which these effects are produced still appears open to question.

The pathology presents little that is characteristic. Conditions found in deaths from asphyxia are sometimes present. The gastro-intestinal tract is apt to be congested, perhaps quite as much from the action of irritant emetics as from the effect of the aconite.

Regarding the treatment of aconite poisoning, it appears that we are rather better equipped for success than was hitherto the case. In the 41 cases referred to by Woodman and Tidy in 1877, 67 per cent. died; and it is noteworthy that neither digitalis, atropia, nitrite of amyl or heat are mentioned as among the agents used. They include sulphate of zinc, finely powdered animal charcoal "as suggested by Headland," the stomach-pump, ammonia, brandy, strong coffee, tea, liniments and friction to limbs and spine, sinapism to stomach, and slight galvanic shocks to heart. They also state that "much has been said about the mutual antagonism of strychnia and aconite, and, judging chiefly by their different effects, they have been regarded as mutual antidotes."

Of 20 cases collected from references in the "Index Medicus" for the past ten years, six resulted fatally. Of these death was reported as occurring in one case in two hours (from two drachms of the tincture), in another in one and a half hours (from three drachms of the tincture), and in one in sixty-five minutes (from one ounce of the tincture, B. P.); time not stated in three cases. In the recoveries the duration of acute symptoms was from one to nine hours, the average being four and seven-tenths hours. In one case of recovery one and one-half ounces of Fleming's tincture had been taken. In another seven and a half drachms of the (U. S. P.) tincture.

Appended is a list of these references, together with a summary of the treatment of each case. Their number is not enough to base statistics upon, but they are of interest as evidencing improved treatment. In these cases the symptomatology was the same as that usually given in works on toxicology.

From the various data now available I would briefly summarize the treatment of aconite poisoning as follows: Empty the stomach with the stomach-tube as soon as possible and wash out thoroughly at the time. If one cannot get a tube, use active emetics, as zinc sulphate, or better still apomorphia. For local measures, tannic acid, charcoal (introduced to the stomach in a dry state, as by kouseals), and oils may possibly be of value. Potassium permanganate might also help if the stomach does not contain food. They are of no use after removal of the poison, and measures to produce this should take precedence of any others. To combat the effect of poison already absorbed, antidotes should be given hypodermically. For this purpose none of the above are of value. In reviewing the reported cases, it seems to the writer that much valuable time was lost in some cases by attempts at medication by the mouth. The tendency to emesis and the altered absorptive conditions of the stomach are the contraindications. For antidotes, digitalis, atropine sulphate, strychnine sulphate, alcohol and ammonia subcutaneously; nitrite of amyl by inhalation; hot and concentrated alcohol, as brandy, by enema; and galvanism for stimulation of the respiratory and cardiac centres, are of value, in the order named. Perhaps galvanism should be ranked relatively more highly. Opium and camphor have also been recommended. As to dosage, the rule of pushing a drug to the point of its physiological action is to be observed.

Regarding other measures, a very important one is that of keeping the patient warm. He should be wrapped in hot blankets. In the use of heaters especial care should be taken to prevent burns, as the

skin is largely insensitive; moreover, the internal pain is so great as to overshadow external pain. A point of practical importance, not mentioned in the text-books, is that of wrapping up the head and applying heaters there. This apparently gave especial comfort to our patient. Elevating the foot of the bed is of some use.

In the treatment during convalescence, a simple diet, as of milk, whites of eggs, arrow-root, ice-cream, etc., is best. Of drugs, protectives and demulcents, bismuth, flax-seed and oils are of value. For tonics, rest, food, fresh air, massage, electricity and, perhaps, strychnia and iron, are of importance, in the order named. While some patients have been reported as well on the next day, it is not uncommon to have convalescence delayed many days, even weeks.

APPENDIX.

CASE 1. P. F. Brick, M.D., of Iowa. *Journal American Medical Association*, 1887, vol. viii, p. 567. Tincture, seven drachms. Recovery. Emetics, morph., gr. 1-2; ex. digitalis, fl. gtt. 6; strychnia sulph., gr. 1-160; brandy, oz. 1; all hypodermically. By the mouth, two gallons of warm water; ex. digitalis, fl. gtt. 20; coffee, pints 11; whiskey, pints 3; ex. nucis vom. fl. drachm 1-2; port wine, pint 1-2.

CASE 2. T. H. P. Baker, M.D. *American Practitioner and News*, Louisville, 1887, vol. iv, N. S., p. 122. About eight drops of concentrated fluid extract. Recovery. Emetics, coffee, whiskey (dessertspoonful). Heat. Friction and sinapism.

CASE 3. C. C. Bradley, M.D. *New York Medical Record*, 1887, vol. xxxii, p. 155. Fleming's tincture, one and one-half ounces. Recovery. Emetics, brandy, ether, digitalis, ammonia carb. Amyl nitrite and warmth.

CASE 4. S. Barnett, M.D. *New York Medical Record*, 1887, vol. xxxii, p. 761. Tr. aconiti rad., one-half ounce. Recovery. Brandy by mouth and hypodermically. Ether. One quart of cold black coffee. Heat and posture.

CASE 5. Clara T. Dereum, M.D. *Medical and Surgical Reporter*, Philadelphia, 1889, vol. lxi, p. 376. Amount not known. Patient intoxicated at the time. Symptoms of acute poisoning. Recovery. Emetics, brandy, ammonia and digitalis by the mouth. Sixty minims of tr. digitalis, hypodermically. Heat.

CASE 6. Byron F. Dawson, M.D. *Medical and Surgical Reporter*, Philadelphia, 1890, vol. lxii, p. 7. Tr. aconiti, amount not known. Child, sixteen months. Marked toxic symptoms. Recovery. Brandy and fl. ex. digitalis, frequently repeated in spite of vomiting.

CASE 7. Benj. Edson, M.D. *New York Medical Record*, 1890, vol. xxxviii, p. 365. Tr. aconiti, two drachms. Death.

CASES 8, 9 and 10. Dr. Edson mentions certain other cases known of, but not treated by him, three of which died. The amounts taken in these were from one to four drachms.

CASE 11. L. M. Whannel. *British Medical Journal*, 1890, vol. ii, p. 791. Tr. aconiti (B. P.), one ounce. Death in sixty-five minutes. Mustard, lavage, heat, ether and brandy subcutaneously.

CASE 12. Ditto. Fleming's tincture, one drachm. Recovery. Zinc sulph., tr. digitalis, m. 20, hypodermically. Whiskey, oz. 1, by mouth; followed by calomel, gr. 8.

CASE 13. T. F. H. Smith. *British Medical Journal*, 1893, vol. i, p. 1109. Fleming's tincture, one teaspoonful. Recovery. Mustard, sp. ammon. comp. (B. P.), tr. bellad., brandy.

CASE 14. Henri E. R. Altenlob. *New York Medical Journal*, 1893, vol. lxvii, p. 358. Ex. acon. fl., four drachms. Recovery. Emetics: atropine and brandy subcutaneously.

CASE 15. G. H. Tuttle, M.D. *Boston Medical and Surgical Journal*, 1891, vol. xxv, p. 678. Tr. aconiti, seven and a half drachms. Recovery. Mustard, digitalis and brandy subcutaneously; digitalis, nux vom. and brandy by rectum; ether and ammonia by inhalation; brandy and ammon. carb., by mouth later.

CASE 16. Ditto. Mentioned by, but not seen by Dr. Tuttle. Tr. aconiti, five and a half drachms. Death.

CASE 17. M. A. Warriner, M.D. *New York Medical Record*, 1891, vol. xxxix, p. 521. Preparation not noted. Four teaspoonfuls. Recovery. Sulphate of copper, digitalis, wine by mouth; whiskey by rectum; whiskey, strychnia, gr. 1-25; digitalis, gr. 1-50, hypodermically.

CASE 18. S. Q. Robinson, Assistant Surgeon, U. S. A. *Boston Medical and Surgical Journal*, 1892, vol. cxxvii, p. 192. Tr. ac. rad., two drachms. Recovery. Apomorphia, stomach-tube, tr. digitalis, m. 25, sp. ammon. arom., m. 45, brandy, drachms 2, subcutaneously, heaters, sinapism to precordia.

CASE 19. Wm. Hardman. *British Medical Journal*, 1893, vol. i, p. 1320. Tin. aconiti (B. P.), thirty minims. Recovery. Salt and water, one and a half hours after poison. Zinc sulph., two hours after poison. Charcoal, brandy and water by mouth.

CASE 20. J. D. Leigh, M.B. *Edinburgh Medical Journal*, 1895, vol. xl, p. 638. Preparation not stated. Five drops. Recovery. Belladonna and strophanthus, champagne, brandy, heaters.

Clinical Department.

A CASE OF ATROPINE POISONING.¹

BY H. F. VICKERY, M.D.

THIS last week I had a case of poisoning of a mild degree from the use of the British Pharmacopœia's unguentum atropinæ upon the intact skin of the breasts of a patient whose child had been dead some days before delivery at term. My object was to prevent the secretion of milk. The nurse had been warned what the symptoms of atropine poisoning were, and no damage was done. The strength of this ointment is eight grains to an ounce. It had been applied to both breasts, with pressure, for three days, when this occurred. The pupils were much dilated with paralysis of accommodation; the throat dry; the heart rapid, (partly, however, from fright, because it was 160 when the nurse took it, and after I talked with the patient a while it came down to 120).

No serious symptoms developed. The disturbance passed away; but it illustrates the fact that ointments are capable of producing physiological effects through the unbroken skin.

It may be added that very little milk was secreted, and that the breasts gave no trouble whatever.

New Instruments.

A NEW MODIFICATION OF THE HIP SPLINT.¹

BY JOHN DANE, M.D., BOSTON.

THE groundwork for the splint shown in the accompanying picture is what has long been known as the "Thomas knee splint." To this has been added a Burrell screw extension, by which it can be somewhat lengthened as occasion may demand. At the bottom there is a windlass and cog-wheel, whereby traction can be made upon the ends of a plaster extension applied to the leg. At the top it is fitted with a pelvic band similar to that now used upon the Taylor hip splints; but so adjusted by means of a hinge joint, that it can be carried sideways when the splint is being put on, and then locked into position by a simple key. The rather broad leathers are sewed to the outside upright, and go thence around the leg and the inside upright as well, lacing up in the front. The upper one is worn as high as possible, the top of the lower should come just below the patella. The perineal strap (when one is necessary) is made of linked window chain, padded with felting and covered with Canton flannel. This is riveted to the splint behind, and fastened in front by being slipped over a hook. When the proper length has been found, all superfluous links of the chain are cut off.

The advantages claimed for the new splint are:

(1) That while it is as easy to adjust upon a sensi-

¹ Shown before the American Orthopedic Association at its Annual Meeting held in Washington, D.C., May 4, 1897.

² Read before the Clinical Section of the Suffolk District Medical Society, February 17, 1897.

tive hip as the common form with two detachable perineal bands, it is more firm when in place.

(2) That it cannot be put on wrongly nor worn too high up, as one so frequently finds the splints which depend for their position upon the length of two adjustable perineal bands.

(3) By replacing the counter-pressure of the yielding perineal straps upon the soft tissues of the groin with that of a rigid metal ring pressing against the tuberosity of the ischium, a firm point of resistance is substituted for a yielding one, and danger from cutting and chafing much reduced.

(4) It is impossible for ignorant parents in out-patient clinics to apply the traction first, and then try and tighten the perineal straps afterwards: the counter-pressure is here the first point established.

(5) It is impossible for a child to loosen the perineal straps and so avoid an uncomfortable amount of traction during the night.

(6) By making the movable perineal strap (where one is necessary) of metal chain, and cutting it to the desired length, it obtains an unyielding and yet flexible means of support and one that cannot be worn too loose.

(7) By means of the broad leathers, passing around both uprights, the leg is held more firmly in the correct position with less constriction than in the common splint with a single upright, and the tendency to genu-valgum or subluxation of the tibia is greatly lessened.

(8) When used for a walking or convalescent splint, the windlass attachment can be cut off. The round ends of the upright are then bent at right angles with the shaft for the last half inch or so and can be slipped into either end of a small piece of tubing fastened to the heel of the shoe. If the length of the upright has been so fixed that the heel of the foot does not quite come into contact with the heel of the shoe, the weight of the body will, when standing, be supported about equally by each of the uprights of the splint. As a consequence, in walking, the customary unpleasant sideways lurch due to the necessity of bringing the centre of weight over the single outside upright of the ordinary splint, is in a great measure done away with.

THE Harben Gold Medal of the British Institute of Public Health, for distinguished services to the Public Health, has been presented to Professor Pettenkofer, of Munich.

Reports of Societies.

CLINICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

E. W. TAYLOR, M.D., SECRETARY.

REGULAR meeting, February 17, 1897, the President, DR. W. F. WHITNEY, in the chair.

DR. E. G. CUTLER and DR. J. W. ELLIOT read a paper on

CHRONIC ULCER OF THE STOMACH; REPEATED HEMORRHAGE; EXCISION OF ULCER; DEATH.¹

DR. LIEBMANN: Regarding Dr. Cutler's case, one thing is not clear to me—that there was any stagnation of food in the stomach, or whether there was any great distention or dilatation of the stomach. We know that, in a complete stenosis of the pylorus, there must be stagnation of the food, and consequently dilatation. However, I may not have grasped that, and would be very thankful to the doctor if he would mention it to me. This case puts me in mind of one of my own, a fatal case, some months ago. It was a man forty years old. When he came to me he did not complain of vomiting, but great pain, constant burning, a boring sensation; but as he was not very intelligent, I had to bring it out that he had pain half an hour after eating. The first time I examined him I found a flat resistance in the region between the umbilicus and the lower margin of the ribs; and later he came back to me after a short interval of improvement, and I could palpate a tumor in the region of the pylorus. I analyzed the contents of the stomach, and found considerable free hydrochloric acid, more than normal. There was very poor digestion of starch. I did several washings-out, and he felt better. In this case there was a considerable stagnation of food after a fast of twelve hours; still I could not make out decided distention of the stomach. The man was not in a cachectic condition. He had lost flesh, like all people who suffer from ulcer; but there was no pallor, no yellowish tint of the skin, and, in short, there was not the aspect of a man suffering from malignant disease. The presence of much hydrochloric acid spoke, as I thought then, against the diagnosis of malignant tumor; and I diagnosed ulcer of the stomach, with hyperplasia or hypertrophic tumor resulting from the ulcer present.

We must remember, though, that the books lay down the rule, that in ulcer of the stomach very rarely there is a tumor to be found, and if a tumor is found, that in itself would speak for malignant disease. Still, there are some cases recorded by Rosenheim and by others where there was no doubt that cancer of the stomach resulted from the ulcer, and that they were both present at the autopsy, the ulcer still persisting, on the ground of which had sprung up a cancer. This man had not vomited except a couple of times; he had never seen any blood escape from his lips. On closer examination he admitted he had seen some dark-colored dejections years ago. I found some hemorrhoids; so I got off the track again. I put him into a private hospital, and commenced to treat him there with much better results than before. I used lavage every morning, and the stomach contents cleared up. After the third or fourth lavage, the wash-water was almost clear; so I thought I had impressed the case favorably, and I was emboldened by this improvement. He felt

¹ See page 54 of the Journal.

hardly any pain. The diet was milk and oatmeal, prepared the way Dr. Fleiner in Heidelberg prepares it. That was all the food I gave him; and emboldened by the improvement, I used a remedy which Fleiner and his old associate Kussmaul recommend highly in bleeding ulcer of the stomach—the use of lavage, and then the introduction in the tube of large doses of bismuth. I commenced to use first about one drachm suspended in water, the patient lying on the stomach so as to spread the powder in close contact with the ulcer. He rapidly gained, and I hoped for the very best. One night I was called in a hurry. The man had had a fearful hematemesis and melena—bloody, tarry dejections. Then I mentioned operation. There was no consent. On the third or fourth night he was taken with another hemorrhage from the mouth, and died with it.

In connection with this case I would say that in the future I would never try to use this remedy, at least not at such an advanced stage of the ulcer. I thought by this treatment I might have brought on hemorrhage. Even lavage would be, in my opinion, a dangerous remedy in these cases. It was lucky the hemorrhage did not occur during my using the lavage.

DR. WHITNEY: I should like to ask Dr. Elliot, when he spoke of the mortality after operation, whether he meant the immediate or remote effects of the operation, and what was the limit of time set for a successful case? Also, in the cases where there had been perforation and the gastric contents were in the abdominal cavity, how long after the accidents had taken place were the operations done?

DR. ELLIOT: These mortalities which I have tried to give are collections of 400 or 500 cases from all sorts of sources; and I cannot give any accurate statement of time. I take it to mean the recovery from the resection until the stomach is in working order. It is the immediate mortality; it is not the remote mortality, I am sure. The shortest time in those cases of perforation was five hours. That case recovered. No case recovered after the perforation had existed twenty-four hours. It was considered, in the judgment of the operators who summed up the cases, that altogether the best chance was in the first twelve hours, rather a poor chance anywhere after twelve hours, and almost no chance after twenty-four hours. I should state that one case was brought to the surgical ward, after a perforation, in such poor condition that an operation was considered inadvisable, and after a long illness the patient recovered.

DR. CUTLER: In reply to Dr. Liebmann's question about dilatation of the stomach, we diagnosticated that, and thought we proved it. In the first place, the person when he came in or shortly afterwards vomited material, according to his story, which he had taken thirty-six to forty-eight hours before. We got in the stomach wash some of the food we had given him twenty-four hours before; and it was pretty evident that his absorptive capacity was not great. I did not feel justified in blowing him up to see how much he would hold. The diagnosis was pretty conclusive from the time I saw him. His personal appearance and history were such that we could not go astray on the diagnosis.

With reference to Dr. Hewes's observations,² on the gastric juice in health, it seems to me they are the most valuable we have had up to this time, as they are the most numerous of any I have in mind at the pres-

ent time. They are very carefully carried out and very valuable, and I think they will give us a good deal of information. He is to be congratulated on the careful and conscientious manner in which he has worked up his subject. I am sure they will be of the very reatest value to us.

THE AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

ELEVENTH ANNUAL MEETING, WASHINGTON, D. C.,
May 4-6, 1897.

(Concluded from No. 2, p. 40.)

SECOND DAY. — WEDNESDAY.

URETHRO-RECTAL FISTULA.

DR. JAMES P. TUTTLE, of New York, read a paper with this title. He first reviewed the literature on the subject, and referred to the comparative rarity of this condition, which consists of a fistulous tract between the urethra and the rectum. The principles underlying the successful treatment of these fistulae, briefly stated, are as follows, and differ but little from those laid down by Duplay:

(1) Remove all obstruction to the passage of urine or intestinal contents through their normal channels. This involves the treatment or removal of rectal or urethral stricture, polypi or other tumors, and the overcoming of sphincteric spasm and obstruction at the anus.

(2) Protect the parts from the abnormal passage of urine or fecal matter and gas.

(2) The therapeutic and surgical treatment of the fistulous tract itself.

The application of stimulating agents or cauterization should be patiently tried before resorting to more radical measures.

After describing the various operations that have been resorted to in these cases, Dr. Tuttle gave a brief report of three cases of urethro-rectal fistula coming under his care. In the first case the fistula opened into the rectum about half an inch above the external sphincter and was large enough to easily admit the end of the index finger. The floor of the urethra was absent to a considerable extent, and required to be rebuilt. There was considerable though not excessive connective-tissue deposit about the opening, and a stricture of the membranous urethra anterior to the fistulous opening. After several days' preparation and treatment to sterilize the urinary and intestinal secretions, he operated on August 30, 1896, as follows:

The sphincter was thoroughly incised and all the cicatricial tissue cut away with scissors, thus freshening the edges of the fistula at both ends. The intestinal wall was then dissected from its anterior attachments, up to a point three-quarters of an inch above the fistula and half an inch to each side. The stricture of the urethra was then operated on by perineal section, the incision being carried backward into the fistulous opening. A flap was then dissected from the soft tissues at either side of the urethra large enough to replace that portion of the floor which had been destroyed. These were sewed together with catgut sutures over a full-sized sound introduced through the meatus in order that the calibre of the canal might be

² Read at the meeting, but not as yet published.

accurately re-established and no pocket left. The fistula being thus closed, the sound was withdrawn and the fresh perineal wound and anterior incision in the urethra left unsutured. The edges of the intestine were then sewed together with chromicized catgut, and the rectum packed with iodoform gauze, a drainage tube having been introduced for the escape of gas. A soft, No. 12 catheter was introduced into the bladder through the meatus and fastened there. It seemed to cause no inconvenience, and was left in for eighteen days, the bladder and perineal wound being irrigated daily with Thiersch's solution. The perineal incision was loosely packed with absorbent gauze and dressed with an ordinary T bandage. Convalescence was uneventful, the perineal wound healing in about six weeks. The patient left the hospital December 1, 1896, perfectly well.

Two other cases were reported by Dr. Tuttle in which the operation proved successful.

DR. SAMUEL ALEXANDER called attention to the fact that these cases not infrequently relapse after operation. Personally, he had been very unsuccessful in operating on this class of fistulae, and he thought that a good result in many instances was due to the fact that the fistula was a very small one and that there was not a great amount of cicatricial tissue.

DR. J. BLAKE WHITE mentioned the importance of keeping the urine from coming in contact with the wound after operation. In urethro-rectal fistulae of traumatic origin an operation would be much more likely to prove successful than in those cases where the condition is the result of a syphilitic or tuberculous infection.

DR. BRYSON could recall only two cases of urethro-rectal fistula which were not of tuberculous origin. The speaker said that when a stricture of the urethra or rectum existed in these cases, it should be removed before any other operation was undertaken, as by removing the stricture we give the fistula an opportunity to heal.

The discussion was continued by DR. FULLER and then closed by DR. TUTTLE.

PRIAPISM.

DR. R. W. TAYLOR, of New York, read a paper on this subject. He stated that this affection may be divided into the following classes:

(1) Priapism observed in infants and children, induced by reflex action, in cases of long, tight, adherent prepuce, of stone in the bladder or prostatic urethra, and of worms in the rectum.

(2) Priapism in adult subjects, symptomatic of stone in the bladder, stone in the prostatic urethra, stricture, cystitis, and observed during retention. In these cases the uneasy or painful sensation is felt in the glans penis, while the body of the organ usually is only moderately congested and sometimes curved downward or laterally. This condition disappears upon the removal of the cause.

(3) Priapism symptomatic of gonorrhea, with perhaps involvement of the corpus spongiosum and downward curvature. This condition is painful and transitory, and may occur several times during the night. In cases of downward curvature of the penis due to inflammatory engorgement of the corpus spongiosum and spasm of the musculature of the urethra, the term *chordee* is applied.

(4) Priapism due to the ingestion of cantharides,

which is a form that is seldom or never seen now, since this drug is so rarely used in medicine.

(5) Essential priapism. The latter form, which was the only one considered by the author, may be divided into four varieties:

(a) Priapism caused by injury to the spinal cord (either high up or low down) and by blows or violence inflicted upon the perineum.

(b) Priapism which is a symptom of cerebral or descending spinal-cord disease.

(c) Priapism which occurs after alcoholic and sexual excesses.

(d) Priapism which comes on a person in ill health in whom it is difficult to obtain data as to local injury and causation, and in which cases there is now a tendency to look upon leukemia as the etiological factor.

Prognosis.—Few definite statements can be made as to the prognosis of priapism of any form. In those cases in which injury to the corpora cavernosa or thromboses can be made out, incisions may greatly expedite the cure. The existence of spinal disease necessitates a guarded prognosis. In very much run-down neurasthenic subjects, in sexual perverts, and in those suffering from leukemia the chances are that the priapism will be very persistent and that relapses are apt to occur.

Treatment.—In surveying the results of treatment of the cases of priapism already published, one is forced to the opinion that nothing like a routine method can be laid down. This much, however, can be stated with emphasis: Chloroform narcosis has failed in every case in which it has been used; ice usually does more harm than good; electricity has no value, and may even be harmful; and leeches to the number of sixteen and forty have failed to produce any amelioration in the condition of the penis, and have been injurious in their depletory effects.

The speaker said that his own preference in dealing with these cases is to resort early to moderate and tentative incisions into the most turgid part, or into parts which are the seat of continuous pain, or into nodular masses in all probability the result of traumatism. It is always good practice in priapism to use either the potassium salt alone or in combination with mercury, when a history of antecedent or present syphilis is elicited. A number of cases are on record in which the condition was relieved by potassium iodide. Bromide of potassium, chloral, belladonna and morphine may be of benefit, especially during paroxysms. Hot baths, hot and cold spinal douches, sponging with hot water, spinal canterization, anodyne poultices and perhaps ice-bags may be found beneficial, but the latter must be guardedly used. Any ephemeral or systemic disorder should receive appropriate treatment.

DR. BRANSFORD LEWIS reported a case of persistent priapism, of a moderate degree, which was cured by ligating the dorsal artery of the penis on each side.

DR. J. WILLIAM WHITE said that in some of these cases, where there is an exudate which constitutes a mechanical cause of the priapism, it might be well, if other measures failed, to try thyroid extract, which modifies the nutrition and sometimes causes absorption to a remarkable degree.

CHRONIC CONTRACTION OF THE PROSTATIC FIBRES ENCIRCLING THE VESICAL NECK.

DR. EUGENE FULLER, of New York, read a paper

with this title. He stated that the condition to which he referred as chronic contraction of the prostatic fibres encircling the vesical neck represented a pathological change in the part, and was totally different from what the French writers (Civiale, Roux, Velpeau and others) have termed "neuralgia of the vesical neck" or "contraction of the vesical neck." The chronic contraction to which he referred, however, bears a relationship to the functional one in that it represents a pathological state which may apparently result from functional contraction or spasm in cases where, owing to some settled disorder of the sexual apparatus, the rectum, the kidney or other organ, functional contraction of the vesical neck has existed as a prominent symptom for a long period. The contraction is permanent, rigid, and does not relax even under profound anesthesia. If a perineal incision is made in such a case, and the finger passed into the membranous urethra in an attempt to enter the bladder, the fingertip will find itself tightly engaged in a ring-like contraction in the deepest portion of the prostatic urethra, where under normal circumstances the canal should be wide, funnel-shaped and elastic, merging itself into the vesical cavity in such a manner that it is impossible simply from the feel to determine just where the urethra ends and the bladder begins. The presence of such a contraction, however, cannot be detected by means of a good-sized sound passed through the urethra. If the surgeon feels carefully with the finger-tip he will discover the urethra just in front of the circular contraction to be roomy and somewhat pouched. The mucous membrane of the entire portion of the deep urethra will ordinarily feel perfectly normal and free from any evidences of previous inflammation. The condition is not associated with prostatic hypertrophy. After the contraction has been thoroughly ruptured or cut through, little evidence will be left to the feel to indicate the nature of the lesion which previously existed. Dr. Fuller said he had thus far been unable to procure an histological examination of the unusual condition, as all of his patients suffering in this manner had recovered as the result of the operation.

The clinical symptoms prominent in cases of this nature, and in fact it might be said the only true symptom dependent on the lesion itself, was an inability, either complete or partial, to void urine. This inability is of gradual development and may at first be intermittent in character, but after a time it becomes permanent. Next in order, the patient experiences temporary attacks of complete retention. For a number of hours he may be unable to urinate. Early attacks of this nature may pass off of themselves as a result of rest, sitting in hot water, etc.; but after a time it will be found necessary to employ a catheter and empty the bladder on one or several occasions before nature will reassert herself. Finally, all power to urinate naturally is lost, and permanent recourse to the catheter is necessary. If pain or other symptoms be present, they are due either to the existence of some disorder of the sexual apparatus, kidney, etc., which has acted as the originator of the trouble at the vesical neck, or else to vesical infection, which has resulted from instrumentation or stagnation of urine due to the retention. These symptoms are of slow development.

A diagnosis of this condition has to be made largely from the clinical history of the case, together with an exclusion of other causes which may produce impediments to urination.

The only treatment for chronic contraction of the prostatic fibres encircling the vesical neck which in the writer's experience had shown any favorable results consists in thoroughly rupturing or cutting through these fibres. This can be accomplished by means of the finger or the knife, as the case may be, introduced through a perineal incision. Perineal vesical drainage should be practised after the operation. This treatment in his hands has been followed by complete disappearance of all subjective symptoms.

Dr. Fuller then detailed the histories of four cases of this affection coming under his observation in which an operation was required to relieve his patients.

DR. CHISMORE said that Dr. Fuller's paper very accurately described a condition which he had met with on several occasions. In all of those cases, with one exception, the result of operative measures was as stated by the reader of the paper.

DR. ALEXANDER said that this condition of contracture of the prostatic fibres had been first called to his attention by Dr. Keyes, and a number of such cases had come under his observation. His own conviction was that the condition did not consist merely of an affection of the fibres, but of the whole substance of the prostate, and that the muscular contracture of the bladder was the active way in which this morbid condition of the prostate manifested itself. The sudden attacks of retention he thought were to a great degree the result of congestion.

DR. BRYSON said it would be interesting to learn of what these contractures consisted, whether of hypertrophy of the tissues normal to the parts, or of a deposit of abnormal, cicatricial tissue.

DR. BANGS said he was inclined to think that the cases described in Dr. Fuller's paper were of quite common occurrence. The etiology had been in his mind traceable to some antecedent inflammation or disturbance of the prostatic urethra. He had also observed that where there is a loss of harmony between the circular and detrusor fibres, with residual urine, the cases are not cured until the bladder is drained and harmony restored between the different muscular parts of the organ.

DR. ALEXANDER said that complete division of the fibres in this class of cases is not always as harmless a procedure as might be inferred from what had been said. Three instances had come under his observation where incontinence of urine followed the operation.

DR. FULLER, in closing the discussion, said that this contracture of the prostatic fibres was not a rare condition, but the cases had never been systematized, and little attempt had been made to ascertain their etiology. The speaker said that while incontinence may result from the operation, it is usually only temporary. All operative interference should be avoided in a case where the vesical symptoms are entirely due to a neurosis, or where there is a suspicion of locomotor ataxia.

TUBERCULAR NECROSIS OF THE PROSTATE.

DR. EUGENE FULLER read a paper on this subject. He stated that tuberculosis in connection with the prostate is spoken of in most text-books as a common occurrence. Most of the writers, however, use the term "prostate" very loosely, it being made to include, besides the prostate proper, the neck of the bladder, the deep urethra and the seminal vesicles, together with their ducts. Dr. Fuller expressed the

opinion that while tuberculosis in connection with the deep urethra and the genital tract is of common occurrence, tuberculosis of the prostate is rare.

DR. CHISMORE said that Dr. Fuller's observations on this subject were wholly in accord with his own. In one case coming under his observation the tubercular disease almost surrounded the prostate, and yet that organ was not involved.

DR. ALEXANDER said that tubercular necrosis of the prostate alone does occur at times, without any involvement of the mucous membrane either of the bladder or prostatic urethra, and the ulceration may find its way into the rectum without any injury to the urethra. During the past year he saw one such case.

A NEW METHOD OF REMOVING POLYPOID GROWTHS FROM THE BLADDER.

DR. GEORGE CHISMORE, of San Francisco, said this method was discovered by him accidentally. It consists of the introduction into the bladder of a litholapaxy catheter attached to an aspirator; by means of suction the growths are caught in the eye of the instrument, and by gentle traction and slight to-and-fro movements they are torn from the attachments and drop into the reservoir of the wash-bottle. This method of removing polypi, Dr. Chismore said, he considered justifiable in cases of emergency, until more radical measures could be resorted to. It is particularly valuable in those cases where the bladder is filled with clots, and retention from over-distention is present, with its attendant suffering.

DR. BANGS said that in one case of polypi of the bladder he had employed applications of hot boric-acid solution with very good success.

DR. BRYSON said he had never seen a papilloma of the bladder which did not eventually prove to be malignant.

DR. FULLER expressed the opinion that the method of treatment described by Dr. Chismore might be advantageously employed in combination with the cystoscope. In some cases he thought a more radical operation was indicated.

DR. WATSON reported a case of recurrent vesical papilloma coming under his observation. He was surprised to hear that there was so little hemorrhage after the operation employed by Dr. Chismore. Personally, he preferred to have the bladder open, so that any severe bleeding could be promptly checked.

DR. CHISMORE, in closing the discussion, said he did not offer the method as a substitute for more radical measures, but one which might prove of value in an emergency. Instead of producing hemorrhage, it checked it.

DR. WILLIAM JUDKINS, of Cincinnati, reported a case of

RECURRENT STONE IN THE BLADDER OF A CHILD.

When the boy was seven years old, a calculus weighing 93 grains was removed by suprapubic cystotomy. Seven months later a second stone, weighing 85 grains, was removed by median lithotomy. An interesting point in connection with the case was the rapidity with which the second stone formed.

DR. CHARLES L. SCUDDER, of Boston, described A CASE OF NEPHRECTOMY FOR CYSTIC ADENOMA IN A PREGNANT WOMAN.

The patient was a woman, three months pregnant,

with a tumor in the left lumbar region. The tumor was aspirated and some fluid withdrawn, which contained, among other matters, a large quantity of bile. A few days later nephrectomy was performed, the left kidney, from which the tumor originated, being removed. The pathologist reported that the case was one of cystic adenoma of the kidney, with a tendency to hyaline degeneration of its contents. The case, Dr. Scudder said, was of interest for several reasons. It is unusual to find bile pigment in a cyst of the kidney. The operation did not interfere with the completion of gestation. A subsequent pregnancy was normal in every respect. It required seven days after the operation for the remaining kidney to secrete what now is the normal amount of urine, namely, about 900 c. c.

DR. G. W. ALLEN, of Boston, made a

REPORT OF A CASE OF HERNIA TESTIS.

J. C., twenty years of age, came to the Boston Dispensary on February 20, 1897, with long-continued gleet and what appeared to be an ordinary epididymitis of three weeks' duration. Four days later a prominent swelling, as large as a hazel-nut, was seen over the front of the testicle. It was conical in shape, and the overlying skin appeared tense and thin. It resembled a tubercular abscess of the epididymis. Upon incision there was a very slight flow of thin pus and a bulging out of soft, yellowish-gray, spongy tissue, which suggested testicle and proved to be such. Some sloughing of the testicle and the skin continued and the former gradually protruded more and more for two or three weeks, by which time the sloughing tissue had separated and a very slow process of repair had set in, which, however, is not yet complete. The incision was enlarged, and several unsuccessful attempts made to cover over the testicle with sound skin. The cavity of the tunica vaginalis gradually filled up with granulations, and there is now a simple granulating surface, as large as a five-cent piece, with a small area of testicle in the centre. A month after the patient's first visit a sore appeared on the prepuce which became indurated in due time and was followed by a secondary roseola. This apparently excludes syphilis as a cause of the orchitis. No evidence of tuberculosis could be discovered.

THIRD DAY. — THURSDAY.

A POSSIBLE AID TO THE DISCOVERY OF THE TUBERCLE BACILLUS IN THE URINE.

DR. JOHN P. BRYSON, of St. Louis, read a paper on this subject. He stated that in the course of his routine work he had accidentally discovered that when tubercle bacilli were present in the urine, they were much more abundant in the residual than in the tidal urine, and in some cases they were found in the former while in the latter they were absent entirely. This fact has led to the suspicion in his mind that the bladder, in some cases, acted as a trap to catch and retain the bacilli, and he thought it even possible, under favorable circumstances, especially where there was blood and pus in the urine and where the bladder did not completely empty itself, that the bacilli might reproduce themselves there.

Recently, Dr. Bryson said, he had instituted some observations in order to learn the relative difference in the residual and tidal urine. These experiments were carried out as follows: The patient was requested to empty his bladder as completely as possible. A

catheter, properly sterilized, was then introduced, and the residual urine, which sometimes consisted of only a few drops, was drawn off. The result of these experiments, taken as a whole, showed a remarkable difference between the number of bacilli found in the tidal and in the residual urine.

DR. EDWARD MARTIN said that his results in searching for the tubercle bacilli in the urine was mostly negative, certainly in the early stages, and sometimes even when there was profuse suppuration. They were only found in exceptional cases.

DR. CHISHMORE said that his experience with cases of tuberculosis of the genito-urinary tract had led him to be very wary of instrumental interference where it could possibly be avoided. The clinical symptoms will often give a strong suspicion of tuberculosis long before the bacilli can be identified.

DR. W. K. OTIS said the tubercle bacilli are only found when there is an opening in some portion of the genito-urinary tract which allows them to escape into the urine. The urine may be full of pus, and yet the bacilli are absent unless there is an open lesion.

THE RELATION OF OXALURIA AND URIC-ACID EXCESS TO GENITO-URINARY INFLAMMATIONS AND DISORDERS.

DR. BRANSFORD LEWIS, of St. Louis, read a paper on this subject. After calling attention to the paucity of literature bearing on it, Dr. Lewis reported a number of cases coming under his observation. He gave the following as his conclusions:

(1) Both oxalic- and uric-acid may appear in the urine, either in a physiological or a pathological manner.

(2) When pathological, they may exert certain injurious effects on the genito-urinary organs.

(3) These effects may be either the inciting of disease where there has been previous health, or they may act by rendering more serious and resistant to ordinary methods of treatment other inflammations and disorders (gonorrheal, etc.) of those organs.

(4) The uric-acid element is not always frankly evident as a causal or complicating factor in such cases; and

(5) When recognized, it is neither more nor less easily controlled than where its disease-manifestations occur in other organs of the body.

(6) When either the oxalic- or uric-acid element is acting injuriously in the ways mentioned, systematic treatment (dietary, medicinal and hygienic) is demanded, and may even take precedence over the local measures that are usually considered sufficient in such inflammations or disorders.

DR. J. WILLIAM WHITE said that he had been in the habit of associating the uric- and oxalic-acid diatheses chiefly with nervous affections of the genito-urinary tract, such as impotence or pseudo-impotence, rather than with the infective inflammations of the urethra. He had observed two cases of hematuria where the presence of the blood was inexplicable on any other theory than that it was due to the uric-acid diathesis.

DR. BANGS said it had long been his practice to study these pathological changes in the urine and their relation to the urinary tract, and it appeared to him that when these acids are present in excessive amounts they render the urethra more vulnerable and more

susceptible to those conditions which we recognize as chronic.

DR. WATSON said he had observed a number of cases of acute urethritis in persons who had never been exposed to gonorrheal infection and whose urine contained an excessive amount of uric acid or urates; those cases, he said, yielded to systemic treatment more readily than an ordinary gonorrhea would have done. He mentioned a case of intermittent hematuria in a man who suffered from persistent oxaluria.

DR. BRYSON said he had often observed that the presence of uric- or oxalic-acid crystals in the urine aggravated inflammatory conditions of the bladder or urethra.

DR. LEWIS, in closing the discussion, said he had observed one case of persistent hematuria which depended on the presence of oxalate-of-lime crystals in the urine. In the treatment of the oxalic-acid diathesis, a meat diet was indicated, while in the uric-acid diathesis, a vegetable diet was preferable. As regards drugs, the speaker said he had often obtained good results from the salicylates, preferably in the form of salophen, which does not disturb the stomach as much as salol.

DR. WILLIAM K. OTIS, of New York, exhibited an INSTRUMENT FOR PHOTOGRAPHING THE INTERIOR OF THE LIVING URINARY BLADDER.

The following officers were elected for the ensuing year: President, Dr. J. William White, of Philadelphia; Vice-President, Dr. James Bell, of Montreal; Secretary, Dr. Wm. K. Otis, of New York.

It was decided to hold the next meeting of the Association at Sing Sing, N. Y., in June, 1898.

Recent Literature.

System of Diseases of the Eye. By American, British, French, Dutch, German and Spanish authors. Edited by WILLIAM F. NORRIS, A.M., M.D. and CHARLES A. OLIVER, A.M., M.D. Vol. 1, pp. 670. Philadelphia: Lippincott. 1897.

This is the first System of Diseases of the Eye written in the English language. It contains about fifty monographs upon various subjects relating to the eye and the surrounding parts, which have been conveniently arranged in four volumes, and each article has been carefully prepared by some one who has shown an especial familiarity with the subject. The first volume, which is a collection of eleven papers upon the embryology, anatomy and physiology of the eye, has only recently been published; and if the three other volumes, which are promised to follow at intervals of several months each, are as satisfactory as the one at present before us, the need of something similar to the "Handbuch" of Graefe-Saemisch in German or the "Traité Complet" of de Wecker and Landolt in French will be no longer felt.

The late John A. Ryder, Ph.D., Professor of Comparative Embryology, University of Pennsylvania, to whom the Section on Development of the Eye had been assigned, has succeeded in making a subject usually so difficult to understand both interesting and easy of comprehension. He describes the human mammalian embryo, the cell-aggregate, and its differentiation into the different germinal layers. The

appearance of the medullary plate and its transformation into the medullary canal are explained, and then the reader is carried rapidly along through the formation of the cerebral vesicles and their off-shoots, the optic vesicles, and their subsequent invagination giving rise to the globe and lens. The progress of the globe from its lateral to the anterior position, together with the formation of the oral and nasal cavities and the out-growths forming the nose and face, are gone into with great thoroughness. The author has not hesitated to introduce many very good cuts, and has borrowed largely from the works of others upon the lower animals, whatever material may seem to him to be necessary to explain obscurities in the text when they arise. The different parts which go to make up the eyeball are then considered separately, and their development traced step by step from the primitive germinal layers. After which comes for consideration the innervation of the globe, the origin and growth of the optic tracts and their connection with the cerebral centres, accompanied by several excellent reproductions of Bernheim's own plates. The description of the development of the extrinsic muscles of the globe and lids concludes this portion of the work.

The next paper, which has for its title "The Anatomy of the Orbit and the Appendages of the Eye," has been very well written by Thomas Dwight, M.D., LL.D., Parkman Professor of Anatomy, Harvard University, who has treated the subject topographically as far as possible, with an endeavor to give an accurate description of the various parts and their relative position one with another. For example, when describing the bony framework of the orbit, he says, "The practitioner needs to know which parts are strong and which are weak, and also what are to be found on the other side of the walls." In view of the importance of a clear understanding of topographical relations, transverse frozen sections at different levels were made especially for this work, and by a more or less diagrammatic representation give an excellent idea of the difference in thickness of the walls, the position of the sinuses and ethmoid cells. A series of antero-posterior frozen sections, as presented, effectually do away with the belief in the existence of a three-sided canal formed by the cornea and closed lids for the passage of tears. That simplicity has been an aim of the writer can be seen from a quotation taken from that part of the paper which describes the capsule of Tenon: "As the complications of this membrane are limited only by the perverted ingenuity of those who describe it, let it be understood that in this paper is meant only the capsule around the globe"; and later, "Although the fibrous tissue of the sheaths of the muscles is undoubtedly continuous with that of the capsule of Tenon, it seems unnecessary to make them expansions of the latter." The relations of the vessels and nerves are carefully explained, and the paper closes with a brief synopsis of the orbital contents as they appear when viewed from above.

It is impossible with the limited space at command to give an adequate conception of the comprehensive treatment that the next section of the work, entitled "The Anatomy of the Eyeball and the Intra-orbital Portion of the Optic Nerve," has received by Frank Baker, M.D., Ph.D., Professor of Anatomy, University of Georgetown. The subject has been handled

very broadly without attempting to adhere to the conventional lines of strict anatomical description. Thereby has resulted a very readable and instructive collection of data following along one after another in logical sequence. Dimensions, both the result of personal observation and what it has seemed fitting to select from the work of others, are recorded with great patience. An extensive knowledge of embryology, physiology and histology has been freely drawn upon, and other sources of information appear as foot-notes, which in themselves form a lengthy bibliography that makes this part of the treatise of value in an historical sense. Theories that have recently emanated from anatomists and physiologists intended to throw light upon questions now being discussed, are given proper consideration; and throughout this paper there is noticeable a commendable spirit of fairness, as well as a moderation in accepting statements which at first might not seem to be sufficiently supported by evidence.

George A. Piersol, M.D., Professor of Anatomy, University of Pennsylvania, has, in his description of "The Microscopical Anatomy of the Eyeball," produced what would form quite a pretentious volume if published separately. The subject has been handled quite cleverly, and is well worth attentive reading. The passage of non-diffusible substances from the anterior chamber into the canal of Schlemm, recently found by Leber to depend upon the amount of aqueous humor which had escaped previous to the injection, clears up obscurities regarding the relations of these parts, but the nature of the communication still remains to be settled, although it is probably by minute clefts between the epithelial elements of the walls of the channel. The question of the existence of dilator fibres in the posterior layers of the iris and their possible connection with delicate spindle cells found in that region is very well presented. The retina must now "be considered to be a peripherally placed portion of the nervous system, and not merely as a complex percipient apparatus of light stimulus," although there still remains much uncertainty regarding the mode of light transmission from the percipient elements to the nervous centres. Every nerve cell is also to be regarded as "an independent individual element," which neither forms networks with its own and other cell ramifications nor has actual union with them. Recent observations have shown conclusively the presence of large neuroglia cells within the supporting tissue of the optic nerve which closely resemble smaller cells found in the fibre layer of the retina. The zonule of Zinn is made up of fibres running in different directions, and entirely independent of the hyaloid and the canal of Petit, that annular-appearing canal, triangular on section, no longer exists as such, but is really a locality of intercommunicating spaces forming a part of the posterior chamber. The writer, in attempting to include within prescribed limits practically all that is accepted in the histology of the eye, has succeeded remarkably well with a difficult task.

Dr. Alex Hill, of Cambridge, England, insists that a correct appreciation of "The Intracranial Portion of the Visual Apparatus," can only be obtained by taking it in connection with embryology, physiology and pathology. The methods of investigation are so intricate and the results obtained so incommensurate with the amount of work done when the territory of

the brain has been invaded that such research is more in harmony with the tastes of the inquiring neurologist than the busy ophthalmologist. Facts, such as are now accepted as true, are ably presented, and the many problems still vexing the investigator offer incentive for further effort in this direction. The anatomical portion of the volume concludes with a paper which deals with "Congenital Malformations and Anomalies of the Human Eye," and the title fully defines the nature of the paper, which is in great part a compilation of much that is reminiscent to those who have been acquainted with the professional activity of William Lang and Treacher Collins at the Royal London Ophthalmic Hospital.

The Physiological portion consists of a series of articles entitled "The Dioptries of the Eye," by Edward Jackson, A.M., M.D.; "The Perception of Light," by T. McKeen Cattell, of Columbia College; A translation of a paper by Eugen Broadhurn, M.D., of Berlin, on "Binocular Vision"; "Normal Color-Perception," by William Thomson, of Philadelphia; and "The Photo-Chemistry of the Retina," by Carl Mayo, M.D., of Heidelberg, translated by J. A. Spalding, M.D. It has not been thought advisable to attempt to give in detail a description of the matter and views embraced by these titles, for that is found to be impossible. Let it suffice to say that the individual writers have succeeded so well with their task that the results justify their selection. This first volume of the promised system is worthy of careful reading from cover to cover, and will undoubtedly create a lively interest in those which are to follow.

W. D. H.

THE LATE DR. WILLIAM T. LUSK.—At a meeting of the medical board of St. Vincent's Hospital, New York, on June 14, 1897, to take action on the death of Dr. William T. Lusk, it was resolved to give expression to the deep sorrow of the members of the board at the death of one who had labored so long and so well for the institution and for its inmates, and of a colleague who, by his courtesy and geniality, had won the high esteem of his associates. It was further resolved to express to the family of the deceased the condolence of the members of the board, and to forward a copy of the record of this action to the medical journals.

THE PROGRESS OF DERMATOLOGY DURING THE VICTORIAN ERA.—In the fourteenth century, as stated by Horner, diseases of the skin were classified under three heads: one consisted of those which could be cured by the use of sulphur; the second, those which could be cured by mercury; and the third, those which the devil himself could not cure. But science has made some progress since Satan's efforts as a dermatologist proved to be futile, and it must be conceded that during recent years few specialties have made such gratifying progress as that which deals with the treatment of diseases of the skin. A history of the progress of dermatology during the Victorian era would make an interesting chapter in connection with all the other records of wonderful achievements associated with the Queen's glorious reign. — *Medical Press and Circular*.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JULY 15, 1897.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

MEDICAL RETICENCE.

In a recent trial in this State a medical witness was obliged by the court to reluctantly testify to facts in a former patient's history, which he had regarded as confidential, and it must have seemed to him that he was made to violate one of the cardinal principles of his profession. What protection has a patient, may well be asked, if even after his death his physician is compelled to reveal secrets which have been reposed in him of a delicate, compromising, or damaging character in a time of sickness and suffering?

No doubt most of the readers of the JOURNAL are familiar with the now celebrated English trial based upon the sacredness of professional confidences, which took place during the past year. Apropos of this trial, Charles Mercier, M.B., of London, has published an admirable paper in a recent number of the English *Journal of Mental Science*, entitled "Medical Reticence," which we wish might be read by any of the brethren who entertain doubts as to their professional duty in refraining from revealing their patients' secrets.

"Only when our inquiries are unrestricted and our means of obtaining knowledge unfettered," Mercier truly says, "can we gain such an insight into the nature of a malady as will justify us in determining on its treatment. For this reason we demand from our patients unlimited candor. This principle we hold justifies us in disregarding the pride of men, and the natural modesty of women. We demand from them answers to our most searching questions on their most private and delicate affairs. We require them to put themselves into unseemly postures, and to submit to humiliating manipulations; and our demands and requirements are unreservedly conceded. But they are conceded assuredly upon the implied understanding that so great a concession carried with it a corresponding obligation, and that obligation is the obligation of secrecy."

He goes on to say that "in these latter days medi-

cal men have become lay confessors. The consulting-room has taken the position of the confessional, as the place where all hearts are open and no secrets are hid."

The conclusion at which Mercier arrives is, "that a medical man is not, under any circumstances, justified in revealing the confidence of a sane patient without the patient's consent." He is careful to make the limitation of the patient being *sane*, because in certain cases, the rule cannot be applied to all confidences of the insane, as, for instance, where the insane person confesses that he has concealed a weapon with a view to killing some one.

We regret that we cannot give a fuller abstract of Mercier's paper, as it goes into many points of interest which arose in the English trial already referred to. The moral which we wish to draw is, that the medical man cannot be too careful in holding the confidence of his patient as a sacred trust, which he must guard and protect as scrupulously as he would his own honor. Expression with us in these days is made so easy that we are too apt to wear not only our hearts, but our thoughts and opinions upon our sleeves. Let us see to it that we cultivate the virtue of silence which is golden, and refrain even from medical gossip about our patients, which, though often toothsome for the moment, is lowering to a high professional standard.

In a previous editorial on "Privileged Communications to Professional Men" (Vol. CXXXIV, p. 349), we commented on the discreditable fact that in some of our States, Massachusetts among others, the courts are allowed to, and do, compel physicians to reveal professional secrets, although lawyers are protected in their refusals. Inequality and injustice in law is, however, no excuse for laxity of personal trustworthiness.

MEDICAL NOTES.

A STATUE OF PIROGOFF.—One of the events of the International Congress at Moscow will be the unveiling of a statue of Pirogoff.

THE GERMAN GYNECOLOGICAL SOCIETY.—The Seventh Congress of the German Gynecological Society was held this year at Leipzig, on June 9th and two following days, under the presidency of Professor Zweifel. Among the subjects discussed were Retroflexion of the Uterus and Placenta Previa.

THE FRENCH CONGRESS OF SURGERY.—The Eleventh Congress of the French Association of Surgery will open at Paris at the Faculty of Medicine on Monday, October 18th, at 2 o'clock, under the presidency of Dr. Gross, Professor of the Faculty of Medicine at Nancy. "Two questions have been submitted to the Congress: first, Contusions of the Abdomen," by M. Demons, of Bordeaux; second, "The Indication for Operation and Treatment of Cancer of the Rectum," by MM. Quenu and Hartmann, of Paris.

BOSTON AND NEW ENGLAND.

THE MASSACHUSETTS STATE BOARD OF HEALTH WILL FURNISH TETANUS ANTITOXIN.—We learn

that the State Board of Health has prepared, at its Bacteriological Laboratory, a limited supply of tetanus antitoxin, which will be furnished to hospitals and physicians on application, as occasion may demand.

J. M. DA COSTA, M.D., LL.D.—At the annual commencement of Harvard University, on June 23d, the honorary degree of Doctor of Laws was conferred upon Dr. J. M. Da Costa, of Philadelphia.

PAUL F. MUNDÉ, M.D., LL.D.—At its recent commencement, it being also the centenary of the Medical School, Dartmouth College conferred the honorary degree of LL.D. on Dr. Paul F. Mundé.

THE NEW HAMPSHIRE STATE ASSOCIATION OF BOARDS OF HEALTH.—The second meeting of the State Association of Boards of Health was opened in Concord on July 12th, with a large attendance. Dr. George Cook, of Concord, presided, and papers were read by Prof. Robert Fletcher of Dartmouth College on "Public Rights vs. Personal Liberty in Health Affairs," and by Prof. F. W. Morse, of Durham, on "The Farm Water-Supply." At the afternoon session papers were read by Dr. L. Pope, Jr., of Portsmouth, on "Pure Milk," and Dr. C. H. Shedd, of North Conway, on "Sanitation of Our Mountain Resorts."

NEW YORK.

THE MORTALITY OF THE HOT WEATHER.—During the week ending July 10th there were reported 966 deaths, an increase of 135 over the week preceding. This increase was, of course, attributable to the hot weather that prevailed. Of the total number of deaths, 215 were due to diarrheal diseases, and there were 545 deaths in children under five years of age; while the number of deaths directly from sunstroke was 10. There were but 2 deaths from measles, the smallest mortality from that disease for many months, and the number of deaths from pneumonia, 65, was also the smallest for a long time. There was one death from small-pox, and none from typhoid fever.

EFFECTS OF HEAT AT THE STATE CAMP.—Last week was a busy one for the hospital corps at the State Military Camp at Peekskill, where the heat was intense; and during the week 657 prescriptions were filled. On Saturday, July 10th, six cases of heat prostration were reported.

COPPER POISONING AT A PICNIC.—The village of Wappinger's Falls, near New Hamburg, on the Hudson, where there are a number of large manufacturing establishments, was in a state of panic for a day or two after its celebration of Independence Day. On Monday, the 5th, a picnic, given in a grove in the vicinity under the auspices of the Catholic Societies, was attended by about one thousand of the inhabitants, and of these, nearly one-half were taken ill with symptoms of cholera-morbus. In consequence, the three physicians of the place, as well as the medical men of all the neighboring towns were very hardy worked. It was supposed at first that the illness was due to ice-cream poisoning, but investigation showed that a con-

siderable number of those attacked had eaten no ice-cream, while all had partaken of ham sandwiches. A chemical analysis of pieces of the ham used for making the sandwiches showed the presence of metallic matter, and it was then ascertained that the ham had been cooked in a boiler lined with copper. Fortunately, no deaths resulted, but some of the patients had quite a narrow escape.

DEATH OF DR. IRA B. READ.—Dr. Ira B. Read, for many years one of the most prominent physicians in Harlem district of the city, died at his residence on July 4th. He was an enthusiastic and active member of the New York State and County Medical Associations, of both of which he was one of the founders. He was graduated from the Medical Department of the University of Michigan in 1867. During the Civil War Dr. Read served in the 101st Ohio Regiment, and his funeral services were held in the Harlem Presbyterian Church on July 7th under the auspices of the Alexander Hamilton Post, Grand Army of the Republic.

Miscellany.

THE RESULTS OF A YEAR'S ENDEAVOR TO LESSEN THE DISPENSARY ABUSE AT THE RHODE ISLAND HOSPITAL, PROVIDENCE.

In the *Atlantic Medical Weekly* for June 19, 1897, is published an abstract of a paper on this subject read before the American Academy of Medicine on May 29th, by Dr. F. T. Rogers of Providence, R. I.

The method pursued at the Rhode Island Hospital, and which was put in operation on April 1, 1896, is the following:

Prominently displayed in the main entrance of the out-patient building is a large placard stating that the services of the attending physicians are given gratuitously and are extended only for such patients as are too poor to pay for the needed attention and that no others will be treated. A similar statement is printed upon each admission card. No patients are admitted to the clinic without a card or letter of recommendation from some medical man, agent of a charitable association or some person well known to the authorities of the hospital, unless they sign a statement that they are unable to pay for such service and desire charitable aid,—save under these exceptions:

- (1) Emergency cases, recent accident or sudden illness.
- (2) The illiterate, evident pauper class, and foreigners who would not be likely to know of such a rule or understand it.
- (3) Any patient concerning whose ability to pay there is a doubt, yet who would possibly suffer by failure to receive immediate attention.

When a patient who is not supplied with a letter of recommendation applies for treatment he is first seen by the admitting officer who inquires of the applicant the name, address, occupation, age, number of children and their ages, and occupation, with the wages earned by the applicant and the children. Next, inquiry is made for the reason for applying for charity and by whom the patient is recommended.

If the replies to the questions are satisfactory, the book is signed by the patient, who thus acknowledges his poverty and asks for charitable aid, and he is admitted to the clinic; if, on the other hand, there is any reasonable doubt as to the truth of the statements, he is told to return with a verification from some medical man or his employer.

The fiscal year of the hospital ends on October 1st, and for the five years preceding, the number of new patients was

1891	1892	1893	1894	1895	1896
5,042	6,392	6,866	8,163	8,469	7,990

This plan was inaugurated April 1, 1896, and was in force during the last half of the fiscal year 1896.

From October 1, 1895 to April 1, 1896, the new patients were	5,038
From April 1, 1896 to October 1, 1896, number who applied	2,952
Rejected during last half of year	7,990
	684
Number of new patients admitted	7,306
April 1, 1896 to April 1, 1897, first year of new plan, number of new patients applying	5,597
Number rejected	1,032
Number of new patients admitted	4,565

The average yearly increase from 1890 to 1895 was \$56, and under the old régime it is fair to estimate that at least this increase would occur and 9,325 new patients would apply for aid during that year. During the first half 5,038 did apply, or at the rate of 10,076 for the entire year, which is beyond our estimate, but at the middle of the year the new order went into effect and the new applicants for the balance of the year were but 2,952, and of these 684 were denied admission.

Among the applicants during the first half of the year there were 107 who were taxed in the city of Providence as owners of real estate for an aggregate of \$310,340; during the second half 77 who were taxed for \$228,040; or during the entire year for just \$38,380 over a half-million dollars.

The maximum amount was \$15,000 and the average was \$2,927. The average per month during the first six months was \$51,000; the largest, \$80,000; while during the last half of the year the average was about \$30,000, and the largest amount during one month was \$52,000.

No one will claim that these people are deserving of free medical service, and we can without fear of contradiction charge a saving of three and three-tenths per cent. to the plan. During the year some sixty old cards were taken from patients who had been in attendance for months, yet who were found to be taxed for varying amounts.

There were 194 who were earning an average weekly wage of over \$14, with either no dependants or were aided largely by other wage-earners in the family.

It is an exceptional case when a man who earns \$56 a month under such circumstances should be dependent upon charity for his medical service.

There were 653 applicants who were told that their statements of financial condition did not warrant their admission to the hospital unless corroborated by a letter from their physician or employer, and of these but 101 were ill enough to return with such a letter. The remaining 552 either got well very suddenly or else could not produce such evidence.

To summarize: Of the 5,597 actual applicants 931, or 16 per cent., were on their own statement not deserving of aid. Of 262 personally investigated cases, 87 were found unworthy.

The attendance upon the dispensary has been lessened over 4,000 new cases per year. If one-quarter of these be allowed to be unworthy, the plan adopted by the hospital has weeded from the ranks of hospital pauperism over 41 per cent. of unworthy applicants.

From a study of the results attained at the Rhode Island Hospital, Dr. Rogers feels justified in assuming—

(1) That the class of people who frequent charitable clinics because they can get free treatment and who think it a bit of shrewdness to thus beat the profession will in a large degree be debarred from further attendance.

(2) That those who seek such advice because they do not know to whom to go, yet who are able and willing to

pay a moderate fee are, by such a plan, without offence, referred to some physician, and another large class of habitual attendants is done away with, lessening the work of the dispensary and increasing that of the profession.

(3) That the worthy poor are in no sense prevented from obtaining needed aid.

Any plan which will do away with the unworthy, lessen the number who are ignorant of the scope of a charitable institution, and care for the worthy, surely has some features to commend it for trial.

The factors which are not affected by this plan are those which concern the hospital and the profession. Hospital corporations sometimes forget that they owe to the profession that which is even a chance to do just this work; the scramble for hospital appointments tends to lead the hospital authorities to think everything legitimate that comes their way. They fail to see why, when so many are anxious to do this work there should be any protest, and I firmly believe that if there were a united opinion among the profession to-day and that personal ambition and personal animosity could be laid aside, the solution of this problem would be in sight.

The man who gives gratuitous medical service from pure philanthropy takes from the profession a certain something which is essential not only to the education of the physician but to his success in life.

Correspondence.

THE GERMAN CONGRESS FÜR INNERE MEDICIN.

SPECIAL REPORT FROM BERLIN.

BERLIN, June 18, 1897.

MR. EDITOR:—The Congress für innere Medizin brings together so notable a body of men that even in Berlin, where private hospitality and other attractions cause a certain dispersion, one has an unusual opportunity for seeing and hearing the leaders of German medicine. Professor Leyden was detained in Bukarest, "crowning his work," as a daily paper put it. His place as presiding officer was filled with much tact by Prof. Oskar Schmidt, of Frankfurt, a. M.

The paper prepared for formal discussion did not excite as much interest as might have been expected. On chronic articular rheumatism Professor Baumbler described so minutely the present knowledge as regards nature, variety and causes, that little more could be said. Ott, of Marienbad, went with equal minuteness into the matter of treatment, but without bringing forward anything new. Rheumatic diseases became more actual when Chvostek and Singer described their investigations, the results of which have already been published. Chvostek insisted, as before, on the absence of bacteria in the local lesions of acute rheumatism, holding, therefore, that the lesions are of toxic origin, the toxins coming from some such source as an intestinal, tonsillar or pleural infection. Hereditary weakness of the joint tissues, traumatism and lesions of nerves are, according to him, important causes of the localization of toxins in the joints. Chvostek recognizes important differences in the clinical picture of rheumatism in different subjects, and denies that it is sufficiently typical to permit us to speak of it as a single disease.

Singer finds bacteria in all cases of rheumatism, not in the synovial membrane or the exudate, but in the per-articular tissues and even in the muscles. These bacteria are not specific, but represent various pyogenic forms. He therefore places rheumatism among pyemias in the broad sense, and believes that angina is a common starting-point. Singer considers scarlatinal and gonorrheal arthritides typical rheumatic affections. Schuller presented specimens obtained by operative treatment of subacute and chronic arthritis. In the hyperplastic tissues he found bacilli in all cases, and often cocci. In the specimens, however, the organisms were so numerous as to suggest the idea of acci-

dental association. Von Noorden reported observations made by him on persons taking the popular lemon-juice "cure" for rheumatism. Some of them took two dozen or more lemons a day, and often expressed themselves as feeling better. Von Noorden found almost no alteration of metabolism, but severe dyspeptic symptoms, with constipation usually developed. Von Noorden spoke of the importance of carrying out reducing treatment in obese persons with chronic arthritis.

Following Professor Unverricht's very able paper on epilepsy, Flechsig reported some interesting observations made by him on the excretion of (sodium) bromide in that disease. A patient taking ten grammes a day for eight days, excreted in that period thirty-nine grammes; one taking nine grammes a day for three days excreted eight grammes, and one taking eight grammes a day for three days excreted only two and a half grammes. Flechsig advised the administration of large quantities of sodium chloride, and the use of vegetable diet, during bromide treatment, in order to assist in excretion.

Eulenbergh, as referee on Basedow's disease, described at length the present position of that symptom-complex. Matthes, of Jena, reported some observations on nitrogen excretion before and after removal of the thyroid in two cases. In both, the excessive excretion of nitrogen was lessened after the operation. Feeding the dried thyroid removed from one patient increased the nitrogen excretion in the other. Magnus-Levy said he had found similar alterations in patients with Basedow's disease after spontaneous improvement, and thought the operation acted by the removal of an injurious organ. F. Müller mentioned cases of Basedow's disease improved by the use of thyroid treatment, and compared them to cases sometimes observed, in which the Basedow symptoms subside as the thyroid grows larger.

Of the addresses by special request, that of Behring received most attention. The subject was "Therapeutics Founded on Experiment." The value of diphtheria antitoxin, Behring thinks, is now established; and he claims that tetanus antitoxin would also be found practically useful if applied earlier. All hospitals should keep it ready for emergencies. Marmorek's anti-streptococcus serum and Maragliano's tubercle-serum were declared useless. Behring does not think we have as yet a remedy for tuberculosis, and is not very sanguine regarding the discovery of such a substance. However, he admits the necessity of further investigation. Behring says the physical and chemical properties of antitoxins will never be known. He put it aphoristically: "It is not antitoxic matter, it is antitoxic force"; a force that may be carried in certain albuminous substances as iron may carry magnetism. Incidentally he asserted that antitoxins cannot be obtained from toxins by electricity.

Liebreich's address on the "Goal of Modern Medicamentous Therapy" was given on the following day, and received equal attention and almost as much applause. Liebreich repeated his well-known views of bacteriology and animal experiments, denied the value of diphtheria and tetanus antitoxins, and insisted on the efficacy of cantharadin as a remedy for lupus. (He has, by the way, a large practice confined to lupus patients.) He accused bacteriologists of erecting theories, making great claims, and then never giving protocols of experiments. He was eagerly taken up and among the most effective of his opponents was Goldscheider, whose demonstration I shall mention later. So far from being humorists, as Liebreich claimed, bacteriologists had never claimed, as far as Goldscheider knew, there could be a tetanus, for example, without cells. On the contrary, they showed the changes induced in the cells by the bacterial products, as well as the preventive action of the remedy. Baginsky defended diphtheria antitoxin on purely clinical grounds, and Behring showed the antiquity of some of Liebreich's alleged proofs. A number of personal explanations followed.

An interesting innovation in the programme of the Congress consisted in devoting an afternoon to demonstrations of cases and specimens. Timed by inexorable sand-glasses,

Ewald and von Jaksch kept the demonstrations going at a rate that was bewildering.

[Pardon the digression, Mr. Editor, but a set of sand-glasses might prove a boon in societies whose presiding officers are more merciful to the speaker than to the auditors. In this Congress they have a set, in different sizes and colors, corresponding to the various lengths of *referate*, paper and discussion, so that all men can see how time flies. To be sure, I have seen the presiding officer tap the glass with his pencil, whether by reason of nervousness or as a study in experimental physics I do not know.]

In demonstrating a little girl on whom he had had a resection made for serous pericarditis, A. Fraenkel made the interesting statement that on opening the thorax, the heart, instead of lying deep in the fluid, as it is supposed to do, floated on the surface. Although the patient is now apparently well, Fraenkel was not over-sanguine as to the ultimate prognosis. Baginsky opposed operations of all kinds, including puncture, in pericarditis.

Goldscheider showed a man with muscular hypertrophy of the leg following femoral thrombosis. In conjunction with Flatau, he showed beautiful sections of the whole spinal cord, and preparations of ganglion cells with various kinds of degeneration. Very striking were those from animals treated with tetanus toxin, with and without antitoxin.

Renvers showed a man with cirrhosis of the liver and hemorrhagic diathesis. He suggested that the latter was due to a poison in the body which under ordinary circumstances would be dealt with by the liver. He has seen a similar condition in a patient with cirrhosis who acquired diphtheria.

Langerhans demonstrated the larynx of a patient who was treated with the new tuberculin. As the lesions seemed very limited the case seemed a promising one, and the treatment was carried out with a persistency that can only be called brutal, as the patient grew steadily worse after the first few days of treatment. Post-mortem, widespread lesions were found in the lung. Langerhans denied that these could have been present when the treatment was begun, and also the suggestion of Petruschky that the patient might have had sepsis, though his statements did not seem to carry conviction to all present.

Among a number of interesting specimens shown by O. Israel was a fetus with enormous edema. The liver was extremely cirrhotic. A skiagram showed very clearly the absence of both rachitic and syphilitic changes in the bones, but Israel considered the liver probably syphilitic.

I can mention only a few of the many papers read. Lenhartz gave an interesting account of his later experience with lumbar puncture. He called attention to the value of the operation in severe chlorosis. The intracranial pressure is always high in such cases, and the removal of some of the fluid (in twenty cases) gave great relief. In tuberculous meningitis he found the bacilli frequently absent. He found that many cases of cerebro-spinal meningitis, and especially rapidly progressing fatal cases, were associated with Fraenkel's pneumococcus, and thought it premature to consider all cases of epidemic meningitis due to the meningococcus intracellularis. Furbringer said that in his later cases he had not found tubercle bacilli as often as before, even with the aid of the centrifuge. As he expressed it, "the diagnosis of tuberculous meningitis by lumbar puncture is of as little value to the physician as the cystoscope or Widal's reaction." Lenhartz punctures with the patient lying on the side, but Furbringer still uses the sitting posture. Kronig thought failure to find tubercle bacilli in spinal fluid was often due to puncturing too high up. He punctures low down for diagnosis, high up for treatment. He showed a needle for puncturing the spinal canal which is free from the risk of aspirating. Lenhartz, in closing, mentioned a case of meningitis with typhoid bacilli (all tests) in the fluid, but no typhoid lesions in the abdominal organs.

A. Fraenkel described the clinical features of acute leukemia, with which he has had so remarkable an experience. He is no doubt right in thinking the disease is

often mistaken for purpura hemorrhagica. Benda, the efficient prosecutor of the Urban Hospital, demonstrated the histological preparations from a number of the cases, showing the entrance of the lymphocytes into the circulation.

P. Jacob, Engel and Pässler reported observations on leucocytosis which have already been published.

A very valuable paper, which must be read in full to be appreciated, was that of Goldscheider on the "Importance of Irritation in Pathology and Therapeutics, in the light of the Neuron Theory."

Perhaps the most important scientific paper was that of Rosenfeld, of Breslau, who went farther than in his well-known work on phloridzin poisoning, and denied the occurrence of fatty degeneration altogether. His method of proving this is as simple as possible. Dogs are starved and phloridzin poisoning produced. The fatty degeneration which occurs in normal dogs is either absent or very slight, depending on the amount of subcutaneous fat in the animal. If, however, starved dogs are fed on foreign fat, say mutton tallow, and then poisoned, fatty degeneration occurs, but the fat in the degenerated cells is sheep fat, as can easily be demonstrated. Similar experiments may be made with phosphorus poisoning, even in lactation, if a bitch be converted into what Rosenfeld calls a "sheep-fat dog," the milk is sheep's milk. So Rosenfeld proves that the fat in so-called fatty regeneration is not the product of cell break-down. There is a degeneration, but not a fatty degeneration, and fat is only found in such cells if there is labile fat in the body (or to a small extent from carbohydrate food). Perhaps this indicates an attempt at the regeneration of the cells.

An interesting case of hepatic intermittent fever was reported by F. Pick, of Prague.

There was an exhibit of apparatus and pharmaceutical preparations, unfortunately rather crowded in small rooms. German pharmacy seems to be making rapid progress in the way of concentrated, not to say appetizing preparations. The only novelty I saw was an improvement on the glycerine suppository,—a neat little wooden cross-piece attached by a string, to keep the suppository in the place where it does the most good (as the circular says). F. Pick showed a very useful instrument for testing the temperature-sense, with which the results can be read off in half-degrees Centigrade, and also an attachment for the ordinary dynamometer which permits it to be used with almost any set of muscles. The sliding microscopes of Leitz, with which one can go systematically over a large section, were very useful in examining the sections of the whole brain, showing its development, by Flechsig, and the sections of the whole cord, by Flatau.

Dr. Kaiserling showed a number of pathological specimens prepared after his method. Some of them are nearly a year old, and all show not only a remarkable preservation of color, but also a striking retention of the natural structural appearance. Quite as interesting in their way were the wax models of pathological specimens made here by Dr. Paul Berliner, certainly the finest of their kind I have seen. Dr. Berliner now has a much larger series than when he exhibited at the World's Fair, made from specimens from Virchow's demonstrations.

Very many "radiograms" were shown, some of them very good. Professor Bianchi had announced a demonstration of his phonendoscope, but did not give it, at least in public.

The entertainment programme of the Congress included an opera (*Hänsel und Gretel*) and ballet at Kroll's, and a dinner at the Zoological Garden. The most effective speakers at the latter were Quincke and Virchow, but in all cases the native custom of beginning the speeches after the soup and having usually two after each course insured the speaker an audience.

It may be permitted to add that foreigners attending the Congress für innere Medizin are warmly welcomed, are certain to find it both pleasant and profitable and to feel in their hearts a response to the toast *Vivat, floreat, crescat!*

G. D.

METEOROLOGICAL RECORD

For the week ending July 3d, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 2,375; under five years of age 952; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping-cough, erysipelas, and fever) 523, diarrheal diseases 353, consumption 240, acute lung diseases 215, diphtheria and croup 73, whooping-cough 21, cerebro-spinal meningitis 20, typhoid fever 18, measles 17, scarlet fever 16, erysipelas 5.

From whooping-cough New York 9, Chicago 5, Baltimore 2, Boston, Providence, New Bedford, Springfield and Everett 1 each. From typhoid fever New York 5, Cincinnati 4, Chicago and Baltimore 2 each, St. Louis, Boston, Nashville, Worcester and Springfield 1 each. From measles New York 11, Chicago 3, Cincinnati, Cleveland, Providence and Lowell 1 each. From scarlet fever New York 9, Chicago and Lawrence 2 each, St.

Louis, Boston and New Bedford 1 each. From erysipelas New York 4, Baltimore 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,992,524, for the week ending June 26th, the death-rate was 15.7. Deaths reported 3,310; acute diseases of the respiratory organs (London) 142, measles 167, whooping-cough 77, diarrhea 68, diphtheria 46, scarlet fever 29, fever 17.

The death-rates ranged from 9.9 in Brighton to 22.3 in Salford; Birmingham 17.0, Bradford 14.4, Cardiff 15.3, Gateshead 12.4, Hull 12.3, Leeds 14.3, Leicester 11.8, Liverpool 20.9, London 14.6, Manchester 19.5, Nottingham 13.0, Sheffield 18.4, Swansea 15.1.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 3, 1897, TO JULY 9, 1897.

The leave of absence to take effect about July 24, 1897, granted CAPTAIN WILLIAM F. LIPPITT, JR., assistant surgeon, Fort Leaveyworth, Kan., is changed, to take effect when his services can be spared by his post commander, and is extended one month.

A board of officers to consist of COLONEL WILLIAM H. FORWOOD, assistant surgeon-general, MAJOR GEORGE W. ADAIR, surgeon, MAJOR WALTER REED, surgeon, MAJOR JAMES C. MERRILL, surgeon, CAPTAIN LEONARD WOOD, assistant surgeon, is constituted to meet at the Army Medical Museum Building, in this city, on Monday, September 27, 1897, at 10 o'clock, A. M., for the examination of candidates for admission to the Medical Corps of the Army.

MAJOR LOUIS M. MAUS, surgeon, is relieved from temporary duty in the office of the surgeon-general of the Army, and will on August 2, 1897, report for duty at Fort Hamilton, N. Y., relieving MAJOR PAUL R. BROWN, surgeon.

MAJOR BROWN, on being thus relieved, is ordered to Fort Keogh, Mont., for duty, relieving MAJOR EZRA WOODRUFF, surgeon.

MAJOR WOODRUFF, on being thus relieved is ordered to Fort Trumbull, Conn., for duty, relieving CAPTAIN HENRY P. BIRMINGHAM, assistant surgeon.

CAPTAIN HENRY P. BIRMINGHAM, assistant surgeon, upon being relieved from duty at Fort Trumbull, Conn., by MAJOR WOODRUFF, will proceed to Chicago, Ill., and report for duty as attending surgeon and examiner of recruits, relieving CAPTAIN NORTON STRONG, assistant surgeon.

CAPTAIN STRONG, on being thus relieved, is ordered to Fort Myer, Va., for duty, relieving CAPTAIN WILLIAM H. ARTHUR, assistant surgeon.

INTERNATIONAL CONGRESS, LARYNGOLOGICAL SECTION.

At a special meeting of the Oto-Rhino-Laryngological Society of Moscow, held on the 21st day of June, 1897, it was decided that a "bureau" should be instituted for the convenience of members of the Twelfth Section of the Twelfth International Medical Congress (Otolological and Rhino-Laryngological Section).

The object of this bureau will be to give all information needed, not only as to matters concerning the Congress, but as to all other matters where our visitors may require assistance or information.

This reference bureau will be open from 7 to 9 P. M., from the 13th to the 19th day of August, in the Doctors' Club (Bolschaya Dmitroffka), and during the meetings in the room of Section Twelve, B (Laryngo-Rhinology).

I. N. SCOTT, President.

SOCIETY NOTICE.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.—The American Association of Obstetricians and Gynecologists will hold its tenth annual meeting at the Cataract House, Niagara Falls, Tuesday, Wednesday, Thursday and Friday, August 17, 18, 19 and 20, 1897, under the presidency of Dr. James F. W. Ross, of Toronto. The railways have granted reduced fares on the certificate plan to all who attend the meeting; the Cataract House has made a reduction from its regular tariff of charges.

WILLIAM WARREN POTTER, Secretary.

BOOKS AND PAMPHLETS RECEIVED.

Gastric Ulcer, Pyosalpinx, Puerperal Sepsis, Vesico and Urethro-Vaginal Fistula, Vaginal Stricture, Operation, Second Pregnancy, Colpo-Episiotomy, etc. By E. J. Mellish, M.D., Chicago. Reprint. 1897.

A CASE OF LIGATURE OF THE INNOMINATE ARTERY FOR ANEURISM.¹

BY GEORGE W. GAY, A.M., M.D.

LIGATION OF INNOMINATE ARTERY FOR ANEURISM, INVOLVING INNOMINATE, SUBCLAVIAN, AND COMMON CAROTID ARTERIES; FAULTY ASEPSIS; HEMORRHAGE ON THE THIRTY-SECOND DAY; LIGATION OF COMMON CAROTID ARTERY; DEATH ON THE FORTY-SECOND DAY FROM REPEATED HEMORRHAGES.

MRS. M., widow, thirty-nine years of age, born in New Brunswick, had been in the Boston City Hospital several times for various affections — anemia, cardiac stenosis, pelvic cellulitis, and movable right kidney — previous to her last illness. The maternal side of her family was phthisical, the mother having died of that disease; otherwise her family history was negative.

The present illness dates back two years, when she first began to notice the three most prominent and most permanent symptoms, namely dyspnea, dysphagia, and painful pulsation at the root of the neck. The difficulty in breathing was accompanied by severe paroxysms of coughing, which often compelled her to sit up in bed for hours at a time. The pulsation or throbbing in the lower part of the neck was attended by a dull aching pain, which extended into the right axilla and through to the back. The dyspnea, the pain, and the throbbing were all very much aggravated by physical exercise, or mental excitement. The difficulty in swallowing had become so marked that solid food could not be taken at all, and she was obliged to swallow liquids slowly, carefully, and in very small quantities at a time to avoid painful choking sensations. She had violent headaches at times, and for several weeks before coming under our care, she had suffered from considerable pain in the upper part of the abdomen, and from a mild diarrhea.

During the past six months all of this woman's symptoms had grown steadily worse, and she had become an invalid, unable to do anything to support herself. She had lost flesh, color and strength, and was in a pitiable condition. Having been under the observation of Dr. M. P. Smithwick for a long time, he, recognizing her disease, as well as her serious condition, admitted her to the hospital on my service October 19, 1896.

The patient was a rather spare woman with dark hair and eyes, a fairly calm temperament, and good courage. To the right of the median line of the neck, just above the sterno-clavicular articulation, was a diffused pulsating tumor about an inch and a half in diameter. The pulsation was plainly seen as well as felt, and was much more violent than upon the opposite side of the neck. The pulsation in the carotid artery above the tumor and in the radials was normal to the finger. No difference could be detected between the arteries in the wrists, either in strength, fulness, or rhythm. No change could be felt in the coats of the superficial arteries.

The tumor was situated underneath the lower end of the right sterno-mastoid muscle, at the usual point of bifurcation of the innominate into the carotid and

subclavian arteries. There was no edema or discoloration of the skin, and no deformity aside from the tumor above mentioned.

A blowing systolic murmur was to be heard all over the cardiac area, loudest at the apex, and extending up the aorta, to and a little above the tumor. No distinct thrill was noticeable. Nothing to be noted about the eyes and ears. The voice was hoarse, and she was troubled more or less with mucus in the throat.

Below the ribs to the right of the median line was to be felt a mass the size of an orange, which was somewhat tender and painful at times, and was thought to be a movable kidney. No signs or symptoms of any other affection were found. The lungs were sound, and the urine was normal.

The diagnosis was a fusiform aneurism of the innominate, subclavian and carotid arteries. To determine its lower boundaries, and to ascertain if the arch of the aorta was involved, Dr. F. H. Williams carefully examined her chest with the x-ray, and has kindly furnished the following report:

"After careful examination of the patient with the fluoscope, both Dr. Munro and myself were confident that the aneurism did not extend below the lower border of the clavicle. A radiograph of the neck and greater portion of the thorax, although not satisfactory as a picture, because the patient moved, showed nevertheless the outline of the portion of the aneurism above the clavicle. The x-ray examination of this case is of interest, since it indicates that aneurism may be detected, when surrounded by tissues, such as muscles, which are much denser than the lung tissue with which in the thorax they are chiefly contrasted; and, further, the statements based upon the x-ray examination were verified at the autopsy."

Rest and all the usual methods of medical treatment having been faithfully tried without giving any permanent relief, the dangers, possibilities, and probabilities of surgical measures were explained to the patient, and the decision of the matter of treatment was largely left to her. After due consideration she decided upon an operation; and it was done in public on Tuesday, October 27, 1896, with the very efficient assistance of Dr. John C. Munro.

Operation. — The patient having been etherized, was placed in the Bigelow chair, hoping in this way to gain more convenient access to the parts, than if she were placed upon the table. A curved incision, commencing over the anterior border of the right sterno-mastoid muscle three inches above the clavicle, was carried downwards and inwards over the left sterno-clavicular articulation to a point three inches below the top of the sternum. This incision was joined by another three inches in length over the right clavicle. The triangular flap, composed of skin, superficial fascia and platysma muscle was raised, exposing the double origin of the sterno-mastoid muscle. Both portions of this muscle were carefully divided upon a director close to the bones. The cellular tissue was dissected away, exposing the sterno-hyoid, and sterno-thyroid muscles. The fibres of these two muscles were separated, not cut, and held aside with retractors. A medium-sized vein crossing them transversely was divided between two ligatures. This was the only vessel requiring ligation before reaching the innominate artery.

The right sterno-clavicular articulation, including about an inch of the clavicle, and as much of the upper

¹ Read before the Boston Society for Medical Improvement, February 22, 1897, and to be published in next series of the Boston City Hospital Reports.

and outer part of the sternum, was removed readily and easily with bone and gouge forceps. A direct and easy access to the innominate was thus obtained. The sheath of the artery was carefully divided between two small vessels plainly seen, thus avoiding any oozing at the bottom of the deep wound, which is always annoying besides consuming time. The innominate artery was easily separated from its sheath with the index finger which passed down to the arch of the aorta below, between the innominate vessels and the trachea and esophagus behind, and between these vessels and the pleura to the outer side. The innominate artery was about two inches in length, and at its upper part was about an inch in diameter, that is, nearly or quite double its usual size. It gradually increased in diameter from the arch of the aorta, its origin, to its termination. Nothing else abnormal was found in the exploration, and three ligatures of braided silk were applied in the following manner: the first was placed three quarters of an inch above the aorta, and slowly tightened. The second was applied half an inch higher up. The third was merely to reinforce the second, and was applied at the same place. The ligatures were all passed from within outward, although there was sufficient space to allow of their being carried in the opposite direction, if found to be more convenient. They were readily placed in position with a large aneurism needle, tied in three square knots, and cut short.

The wound was closed with silk sutures, a few strands of silk at the angle serving as a drain for the first day or two, and a dry aseptic dressing applied. The right hand and arm were wrapped in cotton wadding, and the patient was removed to her bed. She was in good condition. Pulse 84 at left wrist; color good; respiration natural. The operation lasted about an hour and a half, but it was practically bloodless. Only one vessel was divided, and that was done because it was in the way. The innominate veins, the internal jugular vein, and the pneumogastric nerve were not seen during the operation. There was no "foaming" of the cellular tissue, which occasionally gives so much trouble in deep operations about the neck. There were no mishaps of any sort apparent during the operation. Everything was done deliberately and with care; no hurry nor excitement.

The only immediate effects noticed from securing the ligatures were cessation of pulsation in the tumor, the arteries above it on the right side of the neck, and in the corresponding radial artery. She came out of the ether well, and had no vomiting. Complained only of a little soreness at the site of the wound.

About seven hours after the operation a slight pulsation was detected in the right radial artery. It was synchronous with the left radial, but never increased any in strength or volume during the patient's life.

The day after the operation the patient was very comfortable. Pulse 75, temperature 99°. Had no difficulty in swallowing except from the mucus, which gave her a little trouble. No cough nor dyspnea; no dizziness nor headache; no numbness of right hand and arm; no change in right pupil. In short, to all outward appearances, she was doing perfectly well. Took one-twelfth of a grain of morphine under the skin last night.

Fourth day. Patient comfortable. Pulse 80, temperature 99.5°. Wound dressed and drainage removed. It was dry, clean, and presented no signs of mischief

going on underneath. Took food very well, and slept fairly well.

Sixth day. Pulse 92, temperature 100.4°. This being the crucial day for bacteria, the dressing was removed, and the wound found to be infected. The flap was red and swollen. The discoloration was not confined to the suture punctures, but was more general. A little purulent matter was escaping from the angle of the wound whence the silk drainage was removed forty-eight hours before. Thorough irrigation with corrosive solution and peroxide of hydrogen was ordered every four hours, hoping thereby to check the suppuration, if the infection should chance to be superficial.

The patient was very much more comfortable than before the operation. All of her old troublesome symptoms had disappeared. She breathed easily, swallowed readily, and had no cough nor painful throbbing at the site of the aneurism. The operation had thus far produced very little disturbance of any kind.

Tenth day. Wound entirely healed, except at angle of the flap, where there is a small sinus which extends upward under the skin an inch and a half; redness and edema have disappeared; discharge less. Frequent dressings continued. Codeina, in half-grain doses, occasionally at night for restlessness. Takes food well. Stimulants not required. No medicine, except as stated above.

Fourteenth day. Discharge from sinus very slight. Pulse and temperature normal. Is very comfortable in every way; reads the papers as usual.

Nineteenth day. Disturbed by an alveolar abscess due to decayed teeth. Relieved by incision and poultice. Marked pulsation is to be felt over the right common carotid artery near its origin, accompanied by a distinct systolic murmur.

Twenty-third day. Sinus appears to be closing; discharge very slight. Patient natural in appearance, and comfortable. No complaint.

Twenty-seventh day. Had some pain in cardiac region last night. No disturbance in pulse or temperature. In good condition to all appearances. Discharge from sinus very slight.

Thirty-second day. Hemorrhage. Syringed out the sinus this morning; and while debating as to the necessity of enlarging the opening, blood began to well up from the aperture. It came slowly, not in a gush or in jets; easily controlled by making pressure for a few moments with the finger over the upper end of the sinus.

Patient was immediately removed to the operating-room and etherized. On slitting up the sinus an inch, a cavity the size of a small almond was exposed, at the bottom of which was a sinus an eighth of an inch in diameter extending inwards in the direction of the deep ligatures.

In view of the facts, that the secondary hemorrhage in these cases frequently comes from the distal end of the vessel,² and that for weeks there had been distinct pulsation in the right common carotid artery, thus justifying the possibility of that vessel being the source of the hemorrhage, the artery was exposed and tied with a silk ligature about an inch above its origin. Wound closed completely, and the old sinus packed with iodoform gauze. Patient bore the operation well, and was none the worse for it to all appearances.

Thirty-fourth day. Very comfortable day yesterday

² Dr. H. L. Burrell: Transactions of the American Surgical Association, vol. xiii, p. 291.

but pulse and temperature rose steadily all day, the former reaching 108 and the latter 104.5°. At midnight there was a pretty smart hemorrhage, which had ceased before the house-officer reached the ward. No syncope, but a good deal of fright and mental disturbance, as might be expected. She is more feeble, and looks paler than would be supposed from the amount of blood lost. May be partly due to sepsis, although externally the wound looks well enough. Pulse 80 to 108, temperature 97.8° to 99.3°. She is evidently wearing out from the effects of the hemorrhages, sepsis, and mental strain. For restlessness or pain she receives an occasional dose of half a grain of codeina sulph.

Thirty-fifth day. Another hemorrhage last night, more profuse than the other two; and the patient was more prostrated by it.

Thirty-sixth day. Very comfortable; no hemorrhage. Stitches removed from carotid wound, which had healed by first intention. Pulse 100, temperature normal. Pale and weak. Takes food fairly well. No delirium.

Thirty-eighth day. Some difficulty and pain in moving right arm; it feels numb and cold to herself. Suppuration from open wound very slight. No hemorrhage.

Thirty-ninth day. Profuse hemorrhage this morning; quickly and easily controlled by pressure. Steadily growing weaker.

Forty-first day. No more hemorrhage until this morning, which like all the others was easily controlled by pressure. Pulse weak and soft, and with the temperature continued to rise all day, the former reaching 120, and the latter nearly to 105°. Patient weaker, and has been a little delirious at times for past few days.

Just before midnight a severe hemorrhage occurred, from which she did not rally, although the bleeding stopped of itself by reason of syncope of the patient. She was nearly pulseless; sighing inspiration; unconscious. Quick and powerful stimulation failed to sustain her; and she died in about an hour and a half, or early in the forty-second day of the operation and the eleventh day of the hemorrhage.

THE AUTOPSY.

An autopsy was made on December 7, 1896, by Dr. Leary. The following is his report:

Clinical Diagnosis.—Aneurism.

Woman about forty years old. Well developed, well nourished. Operation wound extending along the anterior border of the sterno-cleido-mastoid muscle, five centimetres below angle of jaw to just below the right sterno-clavicular articulation. The wound in its upper portion healed, the portion to the right of the sterno-clavicular articulation closed by stitches. A thin, bloody, watery fluid exuded on pressure. This wound was dissected down upon. The tissues surrounding it were infiltrated with blood, and it extended down to the innominate artery, around which was formed a cavity about the size of a walnut, filled with clotted blood, fibrin and serous fluid. The dissection was continued up the neck as far as the bifurcation of the carotids, and along the chest to three centimetres beyond the origin of the subclavian artery, and from hence down to the heart, the heart and above vessels being removed in mass. At a point about two centimetres above the arch of the aorta and surrounding the remains of the innominate artery, was a thickened mass, in the centre of which was the above-mentioned cavity which corresponded to the pre-existing aneurismal sac.

This cavity contained the remains of the innominate artery, around which were found at a point two centimetres above the arch, two silk ligatures together. One centimetre above this arch was a single ligature, and just below this point the continuity of the artery was lost. The divided ends were shreddy and covered with fibrin. A probe could be passed directly through the innominate artery into the arch of the aorta. About four centimetres above the bifurcation of the innominate, the common carotid artery was tied. The ends of the ligature could be seen projecting, but the remainder of the ligature was concealed by newly-formed tissue. The artery above and below this point was closed by a thrombus. The subclavian artery with its branches—thyroid axis, vertebral, superior intercostal and submammary—were much dilated. All other arteries and veins met with in dissection were also much dilated. Some of these vessels showed small, slightly-elevated, yellowish patches, particularly the subclavian artery.

Abdomen.—No excess of fluid in peritoneal cavity. Peritoneal surface smooth. Intestines and mesentery very anemic.

The appendix about seven centimetres long, lying over brim of pelvis.

Both pleurae adherent to diaphragm. Free in other parts. The lungs showed some emphysema; universally pale; bloodless except around the cut vessels, where there was some staining. The right lung, lower lobe, showed an old, healed area, with adhesion to the chest wall.

The bronchial glands much pigmented, and some of them calcareous.

The pericardium normal.

Heart. Weight, 300 gms. In the right ventricle in the columnæ carneæ was a hard, calcareous mass beneath the endocardium. On one of the mitral cusps, well up towards its attachment, was an elevated, firm, yellowish area about the size of a split pea.

Liver. Weight, 1,080 gms. Bloodless; markings normal.

Spleen. Weight, 140 gms. Pulp slightly increased. Follicles not distinct. Trabeculae and blood-vessels apparently normal.

Kidneys. Weight, 240 gms. Relation of cortex and pyramids normal. In the left kidney was noticed an area, about the size of a pea, containing yellowish, softened material. In the right kidney were several small pin-head areas with the same yellowish material, evidently purulent. In one place, along the edge of a pyramid, there was a row of six or seven of these small areas.

Smears from the contents of these areas showed many pus cells, and cocci occurring singly and in groups.

Stomach, intestines, pancreas and adrenal glands normal.

Uterus normal. Tubes bound down on both sides by adhesions. On the right side, connected with the par-ovarian, was a cyst about the size of an English walnut, with thin walls, and containing a clear serous fluid.

Heart not opened.

The aorta showed several slightly-elevated, yellowish patches, not calcareous, more marked just above the bifurcation into the iliaes. The first left intercostal artery is obliterated just above its origin; and beyond this point is much dilated, as is also a small branch running off from it.

Anatomical Diagnosis.—Operation wound with remains of aneurismal cavity. Rupture of the innominate artery, one end of which had three ligatures. Myocarditis. Arterio-sclerosis with obliteration of lumen of the first left intercostal artery. Multiple abscesses of kidney. Par-ovarian cyst. Acute hyperplastic splenitis.

Cultures.—Operation wound, two colonies of staphylococcus pyogenes aureus; heart, staphylococcus aureus; liver, three colonies of staphylococcus pyogenes aureus; spleen, eight colonies of staphylococcus aureus; kidney, 53 colonies of staphylococcus pyogenes aureus, colon bacillus.

MICROSCOPIC EXAMINATION.

Dr. Councilman reports as follows:

Microscopic examinations of the tissues were made at various places, including the innominate. A section through a portion of the innominate included between the two ligatures shows the media of the artery folded upon itself and cut through at one point. The remains of the ligatures are found in the tissue. The ligature is infiltrated with pus cells and with a few granulation-tissue cells. The artery appears to be necrotic; it contains no cells, and only the remains of the elastic and muscular tissue can be made out in it. The wall of the artery contains very few pus cells, an invasion having taken place at only a few points. In this section of the tissue there are numerous masses of micrococci. These are found principally in the wall of the artery at the point ligatured, and in the remains of the ligature. The section embraces the adventitia and the adjacent tissues. These are all infiltrated with pus cells, bacteria and hemorrhage.

Sections of the innominate, one centimetre above its origin from the aorta, shows at this point small masses of thrombi adherent to the intima. The intima is thickened and degenerated. The media is in high degree sclerotic. The adventitia of the artery here forms a part of the abscess cavity which represented the original aneurismal sac. It is infiltrated with hemorrhage and pus cells, and shows here and there, in the tissue single silk fibres, the remains of the ligature at this point. In the wall of the aneurism itself only here and there portions of the arterial wall could be distinguished. The whole tissue was infiltrated with pus cells and bacteria.

Section of the carotid artery passing through its origin from the innominate shows it to be occluded by a thrombus which extended into the innominate. The portion of the innominate artery included in this section was in high degree degenerated.

The results of the microscopic examination show a high degree of arterio-sclerosis of the innominate artery at the point of the aneurism. The artery at the point of origin of the carotid was also extensively degenerated. The original aneurismal sac was converted into the wall of an abscess, and only the remains of the tissue of the artery could be distinguished in it. At the point of ligature of the innominate the artery was folded on itself, fractured at one place, and the tissue here invaded by bacteria and leucocytes. From the number of bacteria found at this point, it would appear that this probably represented the original point of infection of the artery.

This operation failed because the asepsis was imperfect. The asepsis was imperfect because of the uneven and faulty action of the sterilizer. It was a comparatively new machine, and its work was supposed to be reliable. At that time the failures had not been sufficiently numerous to excite suspicion. Great care was taken in making all the preparations for the operation, as well as in doing the operation itself; and we were at a loss for an explanation of the unfortunate and unexpected result until Dr. Lovett took cultures from the braided-silk ligatures, such as were used in this case, and found staphylococci. He also found, that while the gauge upon the outside of the sterilizer showed a germicidal temperature, a self-registering thermometer inside showed that the temperature was not always raised sufficiently to render the silk sterile. At the autopsy Dr. Councilman found the greatest number of bacteria in and about the ligatures. These facts would seem to afford a reasonable explanation of the infection of this wound, and hence of the probable failure of the operation.

That this patient should live six weeks, and be ten or eleven days in bleeding to death from one of the largest arteries in the body that is ever tied, and the lesion be within three or four inches of the "power station"—the heart—is surprising, to say the least. One would naturally suppose that the first hemorrhage

would be sudden, profuse and fatal; while the fact was, that a moderate hemorrhage seemed to relieve pressure in the arterial system sufficiently to stop the flow of blood without treatment of any kind. Ligating the common carotid artery did no good nor harm. The patient was not disturbed at all by the operation, and the wound was healed in three days. The blood came from the proximal and not the distal portion of the vessel.

The comparatively slight disturbance to the patient produced by this operation was remarkable. Aside from the stiffness and soreness in the neck upon motion or in clearing her throat of mucus, there was very little suffering. She took one-twelfth of a grain of morphia the first night after the operation, and no more sedative of any sort for several days. I can see no reason why ligation of the innominate artery should not be almost as successful as tying the common carotid. It is largely a matter of asepsis, and herein lies the principal advantages of modern surgery in the ligation of arteries. Formerly, as we all know, the dangerous period was that of the separation and expulsion of the ligature. The moment that process is done away with, as in closed aseptic wounds, then all danger from secondary hemorrhage ceases.

As showing the immunity from cerebral symptoms in these operations, allusion may be permitted to the justly celebrated case operated upon by Dr. J. Mason Warren,³ in which he tied both common carotid arteries for an aneurism by anastomosis of the face and neck. The operations were only a month apart, and yet the only unpleasant symptoms following were drowsiness, and a slight faintness on trying to raise his head from the pillow after the second operation. These symptoms were transient. He recovered from each operation in ten days, and was alive and well three years later. These operations were done in 1845, before the days of anesthetics and antiseptics, and hence are of greater interest and value.

The writer tied both common carotid arteries a few years ago for aneurisms in a young man. The operations were about one year apart. No disturbance of any sort followed either operation. Union took place by first intention, and the convalescence was short and satisfactory. He was alive and able to work for about three years after the last operation.⁴

Recent experience shows the importance of applying two ligatures to this vessel to insure complete and permanent closure of its lumen. They should be placed about half an inch apart, if space will allow. The distal ligature is depended upon to permanently close the vessel, and the proximal one acts as a "break-water" to protect the first from the powerful concussion of the arterial current. In Dr. Burrell's case the proximal ligature, knot and all, cut its way through the arterial coats, and was found inside the vessel, the lumen of which had been restored. Had there been but one ligature, the results could be easily imagined. The distal ligature had accomplished its object perfectly.

In aseptic wounds the lesions made by the ligatures are promptly protected by the new reparative material, thus averting any danger from hemorrhage. In Thomson's⁵ case of ligation of the innominate artery with a single ligature of ox-aorta, death from hemor-

³ Surgical Observations, with cases, p. 446.

⁴ Not long afterwards he was found dead in his bed in the morning.

⁵ Cause not known to the writer.

⁶ International Encyclopedia of Surgery, vol. iii, p. 538.

rhage occurred on the forty-second day. No traces of the ligature were found at the autopsy. The vessel was not completely closed, the clot extending through a small chink in the ligatured portion and being continuous with that in the subclavian and carotid arteries. As all of these thrombi were solid, and could not be dislodged with a stream of water from a syringe, it was concluded that the hemorrhage came from the vertebral artery. It is fair to suppose that an additional ligature might have completely occluded this vessel, but owing to the local sepsis the result would doubtless have been the same. And furthermore it should be said, that the aneurism (subclavian) was well advanced toward consolidation. The constriction had probably been sufficient to stop the current in the sac, and that is the object of all operations.

It does not seem wise to divide the innominate artery between the ligatures to relieve axis tension, as has been done with apparently good results, in tying the carotid and other large vessels. The violence of the systolic impact, the strain upon the proximal ligature, and the tendency of that thread to cut through the arterial coats, the unreliable character of the proximal thrombus, the lack of the firm lateral support, which is present in the neck, thigh, and around other large arteries, the fact that the innominate artery is surrounded by loose cellular tissue, suspended, as it were, in soft non-resisting structures, would all seem to militate against the practice of severing this artery for fear of secondary hemorrhage. The writer has divided the carotid artery twice between the ligatures, and the subclavian and brachial once each. The retraction of the ends of the vessels within the sheath was marked and satisfactory in all but the brachial artery, the divided ends of which retracted very slightly, if at all. Union by first intention followed in all these cases, and hence the results were satisfactory.

As to the method of doing this operation, the writer fails to see wherein any great improvement can be made over that so clearly described by Dr. Burrell in 1895.⁶ The only variation made in the present case was in removing the sterno-clavicular articulation with bone and gouge forceps instead of a trephine. The operation was practically bloodless, only one vessel, the anterior jugular vein, being divided between ligatures to get it out of the way. No other large vessel or nerve was seen during the operation, except the innominate artery. The cellular tissue was carefully divided between two forceps by gentle strokes of the knife, instead of being torn or picked out of the way with a director.

The collateral circulation in these cases forms an interesting anatomical study for any one disposed to work it out. In a general way it may be said to become established through the left carotid and vertebral arteries, the Circle of Willis, the corresponding arteries of the right side, also through the thyroid arteries, the intercostals, especially the superior, the mammary, the profunda and princeps cervicis, and doubtless through many other smaller vessels of the arterial system. It is to be remembered that in ligation or other obstruction of any large arterial trunk, myriads of arteries, previously too small to be dignified with a name, take on a sudden dilatation and growth, and become the avenues of a large quantity of blood. The nearer the heart the obstruction is located,

the more pronounced is this change in the vessels. It is in this manner that the nutrition of the brain is maintained at a point which enables it to perform its function under these extraordinary circumstances. Arterial anastomosis is so free in the upper part of the trunk that almost any vessel may be ligated without fear of resulting gangrene. Perfect asepsis is the key to the situation. With that, success is probable; without it, failure may be expected in a majority of instances.

AN INCIDENT IN THE HISTORY OF VACCINATION.¹

BY W. S. EVERETT, M.D., HYDE PARK, MASS.

THE subject of vaccination may have been exhausted long ago so far as any interest attaches to its discussion, and its fabric may be worn threadbare—even to darning and patching—by the attrition of argument by friend and foe. But there are some incidents in the history of the war that it has waged in winning its way to its present unassailable position that are worthy, not only of lasting remembrance, but of being placed fairly and squarely upon some prominent and elevated pedestal, to be observed, known, acknowledged and remembered by all men everywhere. There are some facts demonstrative of its value, and of its power as an annihilator of one of humanity's greatest scourges, that are too valuable and too decisive to be permitted to be forgotten, and that must never be lost to sight or hidden under oblivion's veil.

I have in my possession—and will show it to you by and by, if anybody takes interest enough in it to care to see it—a small gilded picture-frame, some four and a half by six inches in its dimensions, similar to those that are yet sometimes seen hanging upon the walls of ancient dwellings that have come down through successive generations to their present occupants and whose garniture and furnishings have always remained unchanged. They usually contain a silhouette of some ancestral head. This one of mine is a very harmless and innocent-looking little affair, in its diminutive quaintness, but connected with it is a bit of history that, it seems to me, justifies an attempt to rescue it from obscurity and to make it known to the world. Instead of the ancestral silhouette, there is fitted to it a piece of paper or of parchment I am unable to determine which—on which is written, in an elliptical space which is bounded by a huge serpent whose extremities are made to meet, in a bold, distinct, and though small, a clearly legible hand, a brief legend, which, I should think, in connection with this topic, might make it of interest to medical men. And so I have brought it here for you to look at, if you wish.

Tradition tells us that there was a banquet here in Milton on the 25th day of October, 1809, that was attended by a notable gathering; that chief among that company, and in whose honor it had been planned, were twelve children—eight boys and four girls. The archives of the town of Milton have carefully preserved a record of the transactions that led up to it and Rev. Dr. Teele, in his "History of Milton," has collated the facts and so arranged them that they will always be accessible to those who shall be interested in their perusal. The circumstances that had brought

⁶ Op. cit.

¹ A paper read at a meeting of the Dorchester Medical Club held at the house of Dr. H. P. Jaques in Milton, March 11, 1896, and published by vote of the Club.

that company together, and had made that day a general holiday, were these:

The position of vaccination as a preventive of small-pox was not as firmly established in 1809 as it is now. It had its friends and its advocates, and it had its opponents and its foes. We, who are strong and confident in the assurance of its protecting power, but who yet meet many opponents who are ready to contest every claim that is made for it still, can hardly realize the bitterness with which it was then assailed. Its friends here in Milton were sufficiently enterprising, resolute and progressive, to avail themselves of its protection, and to subject it to the most rigid tests.

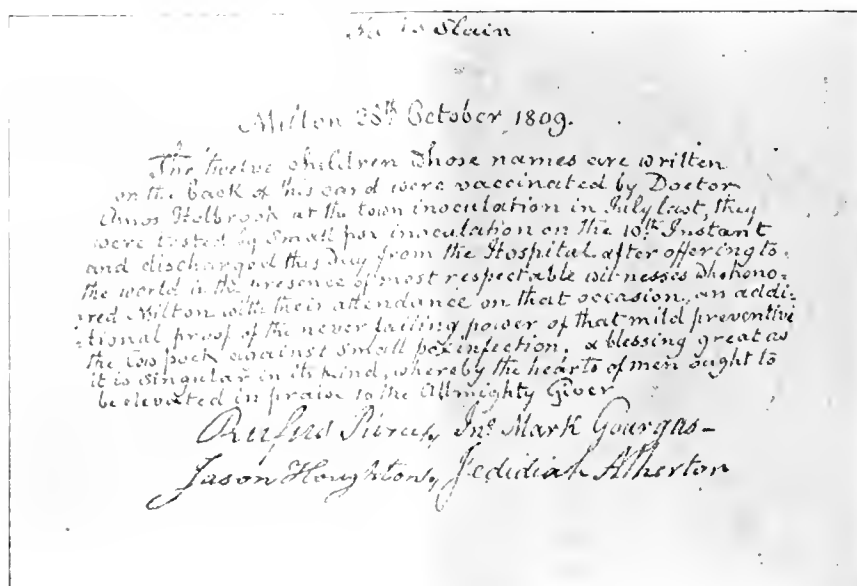

The town records will help us now. It is there on record that at a town-meeting held July 8, 1809, a committee was chosen to take into consideration any

kine pock, and might be so inclined, might repair to be treated with inoculation from small-pox itself.

September 25, 1809. At the special town-meeting held this day, it was "voted to procure a place for a hospital where persons should repair who were to be tested with small-pox inoculation, and no person should be allowed to leave the hospital without a certificate from Dr. Holbrook," who, the committee had arranged, should superintend the whole transaction.

We hear no more from the committee till October 30th. But great things had been going on. They then made their final report at a town-meeting held on that day. They reported that the parents of twelve children had been found who were willing that their children should be tested with small-pox inoculation.

How in the world the parents of twelve children

measures for inoculating with kine pock, such individuals as had never had small-pox, and to report at an adjournment of this meeting to the last Saturday in August. August 26, 1809, this committee reported "that they had procured certificates from respectable physicians calculated to remove all doubt that the kine pock — if really had — is a perfect preventive of small-pox." They had also agreed with Dr. Amos Holbrook to inoculate with, and carry through said kine pock, any inhabitants who might wish to secure themselves against small-pox. Under this arrangement, 337 persons were so inoculated.

We come now to a fact that shows the spirit of the community that was represented at that town-meeting, and the determined character of the men who were having the matter in charge. That committee evidently were not chosen at random nor without due consideration of their fitness for the duty and service that was required. They declared at that same August town-meeting that they should not feel that their trust had been faithfully executed, until some decisive test had been made, and some persons tested with small-pox inoculation; and they made a request that a special town-meeting be called in September, to appoint a place where persons who had been inoculated with

could be found, in the state of feeling that then existed in regard to vaccination, who could be induced to submit their children to this crucial, if not cruel test, was one of the many marvels of that excitable period, and is beyond our comprehension now. But they were found; and it can only be explained upon the theory that great trials develop great characters, and that a victim is always ready for the sacrifice, when a great principle demands a great defence. These twelve children were taken to the house of one Stephen Horton, who had contracted to make his house a hospital for the occasion, and to have the care and custody of the children during the period that they were confined there. For this service he was paid twenty dollars. At his house, on the 10th day of October, 1809, in the presence of "respectable witnesses" as the record has it, they were inoculated with small-pox virus obtained from Dr. Welch, of Boston, who testified to having furnished pure small-pox material for vaccination.

The respectable witnesses to this transaction, were the President of the Board of Health of Boston and their physician, and others whose names are appended to the certificate.

The committee made their final report on the 30th, as has been stated, and they reported that these twelve

children had been inoculated with pure small-pox material on the 10th inst., had been kept under strict observation and surveillance until the 25th, when they were discharged, without a single instance having occurred that presented any indication of the disease.

The town record modestly refrains from any allusion to the pomp and ceremony attending their discharge. But it was thought that such an occasion was deserving of a suitable recognition, and so the ovation that has been alluded to was planned.

The final act in the demonstration of that October afternoon was the distribution or presentation to each of those twelve children of a certificate similar to the one I have in my possession now.

The committee, in making their final report on the 30th, state that such a certificate had been distributed to each of those twelve children who had been discharged from the hospital on the 25th; and a statement of the whole transaction was prepared and is preserved in the archives of the town, where it has lain for nigh a century, and where it is to be found to-day.

And that is all. The occasion has passed. The tumult, the excitement, the agony of suspense are gone. Who approved, and who opposed this measure, matters not now. Friend and foe have ceased contending; they who demanded this trial of faith, and the victims who offered the sacrifice, are silent; and none are now living who witnessed the scene.

But the fact remains, immovable as the mountains, unending as eternity, unchanging as truth. Twelve children here in Milton have been vaccinated with bovine virus, have subsequently been inoculated with pure unadulterated, unmitigated, unmodified virus of small-pox itself, and have escaped without a sign or a manifestation of the disease. The facts are fully authenticated. They are beyond denial. They are beyond dispute. There they stand. And there—like Bunker Hill and Lexington—they will stand forever.

It is, of course, quite possible that this may not be the only instance where this test of the power of vaccination has been applied, though no such application of the test has come to our knowledge thus far. If there are other instances, and if they have resulted as favorably as in this instance, they simply render the test more decisive; if there have been failures, they have not been made known; and if this should be found to be the only case where such an experiment had been tried, then this simple and unpretentious little certificate (a representation of which is shown on page 78) and such of its fellows as have been preserved, become the lonely, if not the only, silent and yet eloquent, undisputed and indisputable witness, after all these many intervening years, of one of the most momentous happenings of modern times.

The legend within the ellipse is here transcribed:

MILTON, 25th October, 1809.

The twelve children whose names are written on the back of this card were vaccinated by Dr. Amos Holbrook at the town inoculation in July last; they were tested by small-pox inoculation on the 10th instant, and discharged this day from the Hospital, after offering to the world in the presence of most respectable witnesses who honored Milton with their attendance on that occasion an additional proof of the never-failing power of that mild preventive, the Cow Pock, against small-pox infection, a blessing great as it is singular in its kind, whereby the hearts of men ought to be elevated in praise to the Almighty Giver.

The signatures to this certificate are

RUFUS PIERCE,
JASON HOUGHTON,

JNO. MARK GOURGAS,
JEDIDIAH ATHERTON.

All these are names that have stamped their impress upon Milton history. The name of Gourgass has disappeared; but the names of Pierce, Houghton and Atherton are well remembered still.

Over the head of the serpent whose body surrounds this legend, is the inscription, "He is slain."

The names of the twelve children who were subjected to this test and are referred to in the certificate as being on the back of this card must not be omitted. They are—

JOSHUA BRIGGS,
THOMAS STREET BRIGGS,
MARTIN BRIGGS,
CHARLES BRIGGS,
CATHARINE BENT,
RUTH C. HORTON,

SAMUEL ALDEN,
BENJ. CHURCH BRIGGS,
GEORGE BRIGGS,
JOHN SMITH,
SUSANNA BENT,
MARY ANN BELCHER.

They are all now dead. How many of the certificates that were distributed to them on that afternoon have been preserved is not known.

Dr. Teele has copied one into his history, and perhaps others may be heard from hereafter, though these are all of which any knowledge has yet been obtained.

The one copied by Dr. Teele differs somewhat in its phraseology, while it certifies to the same fact.

The one here shown was not one of the twelve that were given to the children. It never left the posses-

sion of one member of the committee that superintended the whole transaction, and by whose authority they were prepared and issued, and whose names are appended thereto. This particular one was retained by Jason Houghton, whose name appears among its signatures, and was preserved by him with great care, so long as he lived, as being among the most valuable relics of his time. It had its place in his farmhouse (a picture of which is shown, as being of some interest in this connection) there upon the banks of the beautiful Lake Wissahickon (now a part of our park system) here in Milton, during his subsequent life, a period of nigh forty years. It then remained among the family relics, until, two generations afterward, the estate changed ownership, and the treasures and heirlooms of a century and a half, were broken up and dispersed. Since that dispersion it has been in my hands. Its genuineness cannot be questioned. It represents an undoubted fact of history. It is just what, and all, that it claims to be. And it has seemed to me to be of sufficient importance and significance to be worth making its existence known.

A METHOD OF INDUCING LABOR. — Kossmaun recommends the injection of a drachm of glycerin within the cervix to induce labor.

A SEXUAL STUDY OF THE SIZE OF THE ARTICULAR SURFACES OF THE LONG BONES IN ABORIGINAL AMERICAN SKELETONS.

BY GEORGE A. DORSEY, PH.D.,

Assistant Curator of Anthropology, Field Columbian Museum,
Chicago, Ill.

It seems to be pretty well established that there is a fairly distinct and constant line of demarcation in the size of the head of the humerus and the head of the femur for the two sexes in European skeletons. That this would hold good for these bones in prehistoric or savage races has been questioned by some anatomists. From the literature at hand I am not able to learn that the subject has been investigated with any degree of fulness, and indeed statistics on the subject for European skeletons even are not numerous.

The most general reference to the subject that I have seen is to be found in a paper by Prof. Thomas Dwight.¹ Speaking of the sexual differences of the arm, he says: "The articular ends of bone of both arm and forearm come to the rescue, but I regret that I have no series of measurements large enough to quote." And in another place he says:

"The small size of joints is characteristic of woman. They are the greatest diameter of the head of femur and the greatest transverse breadth through the condyles. The average diameter of the male head is 4.8 cm., that of the female 4.15 cm."

The only other observations, in addition to those of Professor Dwight's, with which I am acquainted are to be found in the valuable paper of Prof. David Hepburn on the Femur.² In that paper he gives the measurements of the diameter of the head of the femur in the skeletons of a large number of different races. His results are very interesting, for they confirm, at any rate so far as the femur is concerned, the results which I have reached in the present inquiry. Professor Hepburn has not arranged his measurements so that the mean average diameter of the two sexes can be seen at a glance, but from his tables I have selected such races as are represented by skeletons of both sexes, and have then determined the average for each sex, results of which are as follows:

Maori, males (5) 45 mm., females (1) 42 mm.;
Australians, males (6) 44 mm., females (1) 33.5 mm.;
Hindoo, males (2) 47 mm., females (1) 36.5 mm.;
Laplander, males (1) 42 mm., females (1) 38.5 mm.;
Eskimo, males (1) 46 mm., females (1) 40.5 mm.;
Andaman, males (4) 37 mm., females (2) 35 mm. A comparison of these figures, together with mine, with those for Europeans, lends a suggestion to the possibility that, as in many other parts of the skeleton, sexual differences in the size of the articular surfaces have gone on further in the European than they have in the lower races of men.

The largest single diameter found by Professor Hepburn was 57 mm., in a British male; the smallest was 34 mm., in an Andamanese female. The maximum and minimum diameters determined by me are 54 mm. and 38 mm. In none of the Andamanese skeletons did the diameter of the head of the femur reach 40 mm. This is as we should expect, for the Andamanese have an average stature of only 1.492 mm.,³

and are, therefore, among the shortest people in the world.

The following two sentences from Professor Hepburn are especially interesting: "This diameter [of the head of the femur] was also found below 40 mm. in two Australian, two Negro, two Hindoo, two Lapp, two Sandwich Islander, and one dissecting-room femur; and in all of these cases they were from females. Except among the Andamans, no male femur had a head diameter less than 40 mm."

With the view of testing the observations of Professor Dwight on the European humerus and femur, and of Professor Hepburn on the femur in the tribes of the Pacific and Indian oceans, I have examined 135 skeletons which come from three widely separated regions of America. The first group comprises 19 Kwakiutl, 15 Sanitch, and 6 Chinook skeletons from the Northwest Coast; the second group is from the prehistoric mounds of Ohio, and comprises 27 skeletons; the last region represented is Peru, and includes 6 skeletons from Cuzco, 7 from Arica, and 50 from the Necropolis of Ancon. These may be regarded as fair representatives of the better class of aboriginal Americans. I may note also that I have examined only adult skeletons in which all the epiphyses were firmly united; and the sex in every instance has been determined by the pelvis, no skeleton having been considered in which the pelvis was not present.

After some deliberation I decided upon three measurements, namely, the maximum diameter of the head of the humerus and the head of the femur, and the maximum transverse diameter of the head of the tibia through the condyles. It would probably have been as well to have taken also the transverse diameter of the lower end of the femur through the condyles; but as Professor Dwight had found this measurement "less conclusive," I substituted the head of the tibia in its place. It would have made an interesting study to have noted also the size of the articular surfaces in connection with the length of the bones, but I did not have the time for this. I am convinced of the correctness for American bones of Professor Dwight's observation, "that in the woman there is a fairly regular increase in the size of the head, corresponding with the increase in the length of the femur." But I am not equally well convinced of his second observation, that "among men this is not so."

Before considering the three sets of measurements I may mention that in a recent study on the scapula of the Northwest Coast Indians, I measured the dimensions of the glenoid cavity in 20 specimens and found that in the males it measures 41 by 30 mm., and in the females 35 by 25 mm. It was shown, furthermore, that in not a single instance did the longest female cavity equal the shortest male cavity, and that in only one instance did the broadest cavity in the female series equal the narrowest of the males. One other point should be mentioned here, as the facts are brought out in the measurements but are not shown in the tables. There seems to be no uniformity in the comparative size of the heads of the humerus and the femur in the same skeleton. Thus, in the male series of the Northwest Coast tribes, the head of the humerus exceeds in size the head of the femur seven times, while the head of the femur is the larger nine times; in the female series each is the larger just eight times. This same observation holds good for both the Ohio and Peruvian series.

I. NORTHWEST COAST INDIANS.

As the measurements from the three peoples from this region are so nearly alike, they may properly be considered together; and we have, therefore, 21 males and 19 females. The comparative frequency of distribution of the diameters of the articular surfaces for both sexes may be seen in the following table:

TABLE I.—NORTHWEST COAST INDIANS.

Humerus.			Femur.			Tibia.		
Mm.	M.	F.	Mm.	M.	F.	Mm.	M.	F.
39		2	39		2	65		2
40		6	40		4	66		3
41		4	41		5	67		5

It is seen that the line of separation is clean cut, except for the femur; here a single measurement overlaps. The other two series are emphatic in their results. Thus, if we take the average for both sexes for the humerus as 43.5 mm., it will be seen that the measurement of no female humerus exceeds it, while that of no male falls below it. The range of variation for the tibia is, as we might expect, greater than that for the other two bones.

II. MOUNDS OF OHIO.

The skeletons here represented are from ancient graves and mounds in the Little Miami Valley, and are all prehistoric. Although two or three localities are represented, the material is so homogeneous that it may be considered as a whole. The measurements comprising 20 males and 7 females, are distributed as shown in Table II.

The line of demarcation here between the two sexes is not quite so sharply drawn as it was in the preceding one. It is to be noted, however, that the greatest amount of agreement is, as we might expect, in the

diameter of the head of the tibia. For the humerus and femur the differences between the two sexes is still a decided one and sufficiently marked to be of great value.

III. PERU.

Of the Peruvian skeletons, six are from the vicinity of Cuzco, being equally distributed between the two

sexes; seven from Arica, three being males and four females; and 50 from Ancon,⁴ each sex being equally represented. Although skeletons from the first two localities are slightly taller in stature than those from Ancon, the difference does not affect to any appreciable extent the averages between the two groups, so that I have put them into a single table. (Table III.)

The result here shown is very satisfactory and even conclusive. Thus, in the humeri of 31 females there is not a single measurement which equals the lowest of the male series. The line of separation between the two sexes for the femur and the tibia is not so sharp as it is for the humerus, but it is very nearly so and in fact is more so than we might expect when we take into consideration the fact that the skeletons from Ancon are from people of exceptionally short stature, while those from Cuzco and Arica represent people of rather more than average stature. Another point which may be noted, although of no particular consequence, is the fact that in the South American humeri no measurement exceeds 48 mm., although in both the Northwest and Ohio groups some of the measurements exceeded 50 mm.

Combining the results as shown in Tables I, II, and III, we have Table IV, which gives the distribution for 135 skeletons.

For reasons which have already been given, this

⁴ It may be proper to state that the Ancon skeletons were taken at random from a much larger number which are in the Museum. The number 50 was arbitrarily chosen because it was thought sufficiently large to be considered as representing the entire series.

table is not perfectly conclusive in its results, for the skeletons from Ancon are from very short people, while those from the Ohio Mounds and the Northwest Coast represent people who are above the average in stature. For this reason we might be prepared to find the largest measurements of the females of North America equalling or surpassing the smallest males from Ancon. Thus, to take a single instance, if we

analyze the figures given for the humerus we shall find that of the three females with a diameter of 43 mm., two come from the Northwest Coast and the other one from Ohio; while of the 13 males with a diameter of only 44 mm., three are from the Northwest Coast, one from Ohio, and nine from Peru, seven being from Ancon and two from Cuzco.

But even if these considerations be waived, the results of Table IV are remarkably decisive. Thus, if the maximum diameter of the head of the humerus of any American skeleton measure 44 mm., the chances are extremely great that it is a male; if it measure 45 mm., it is a male to a practical certainty. The inferences to be drawn from the measurements of the femur seem almost, if not quite, equally valuable; and it would almost seem that we could determine sex from the femur alone with a great deal more certainty than we could from the skull. After Professor Dwight's disparaging remarks about his results from measurements through the condyles of the femur, I was quite unprepared for the results which have been derived from the tibia. The range of variation is, to be sure, greater than it is for either the humerus or the femur; and this, it may be repeated, is largely due to the dis-

crepancy in stature between the North and South American skeletons, but the dividing line for the two sexes, between 71 mm. and 72 mm. is almost as sharp as it is in the femur, and makes the tibia a valuable aid for the determination of sex.

In conclusion, apart from the value of any one of these three bones as important and practically decisive factors in determining sex, we must not lose sight of

the original purpose of this inquiry, which was: What light do American skeletons throw on the theory that the articular surfaces are larger in the males than in the females? or to put it in Professor Dwight's words, "that the small size of joints is characteristic of woman"? The answer is, perhaps, best given by repeating the averages as determined in Table IV.

The average maximum diameter of the head of the humerus in the male is 46.3 mm.; in the female, 37.7 mm. The average maximum diameter of the head of the femur in the male is 47.3 mm.; in the female, 41 mm. The average maximum diameter of the head of the tibia through the condyles in the males is 78.5; in the females, 67.4 mm.

THE STATUE OF CHARCOT, by the sculptor Falguière, is nearly finished, and will soon be erected at the Salpêtrière.

ON THE OCCURRENCE OF RETINAL HEMORRHAGE AFTER MIDDLE AGE, AND ITS BEARING ON THE DURATION OF LIFE.¹

BY HASKET DERRY, M.D., BOSTON.

THE history of the following case will serve as a fitting introduction to the present paper.

Mr. X. Y., aged sixty, consulted me a few years since. From having had excellent vision for objects both far and near, assisted, of course, in regard to the latter by glasses corresponding to his years, he had only recently come to notice a considerable difference between the two eyes. On testing him in regard to this point I found that, while the vision of the left eye was normal, with the right eye he could barely count fingers held ten feet away. There was no external change, but the ophthalmoscope showed the presence of innumerable spots of fresh hemorrhage into the retina, scattered over the entire field, as well as its periphery as in the immediate vicinity of the nerve.

Mr. Y. had been for years actively engaged in public life, had not long previously undergone much excitement and fatigue in contesting an important election, and had only recently acted as counsel in a protracted and excited trial. He was a man of large frame and full habit, weighing probably two hundred pounds or more. He paid no attention to physical exercise, and had for three years enjoyed no vacation whatever. Numerous affairs of consequence were even then engrossing him.

I felt justified in assuring him that the disease of the eye was probably the forerunner of something worse, unless he wholly changed his course of life. Weakened retina implied weakened cerebral arteries, and it was easy to realize what that meant. I advised complete rest for several months, as well as a change of surroundings.

The patient viewed the situation intelligently, and talked it over for an hour, dwelling on the absolute necessity of keeping his numerous professional engagements, and the consequences that might ensue from any neglect on his part of the important interests that had been confided to him.

This was in July, and I never saw him again. A year from the following February he came out of the court-house, in which he had been trying a case, started to walk home, but quickly grew confused, staggered, and had to be placed in a carriage. He grew rapidly insensible, manifested all the signs of an attack of apoplexy, never regained consciousness to a full extent, and died on the third day.

The subject of the connection of retinal hemorrhage with the condition of the general health is not dwelt upon by writers on ophthalmology at any length. I have looked over all the accessible literature that has appeared since the invention of the ophthalmoscope, and have been surprised to find how little is said in regard to the matter. The subject is ordinarily dismissed in a few words. All authors are, however, agreed that, occurring in the aged, the symptom is an ominous one. While its effect on sight need be but temporary, capable as it is of a considerable measure of repair, and ordinarily affecting only a single eye, it has a bearing on the duration of life that is full of significance. It may betoken an atheromatous condi-

tion of the cerebral arteries, and be due to a similar state of things in the retinal vessels, which, however, the ophthalmoscope fails to detect. Or there may be a cardiac lesion, ordinarily hypertrophy of the left ventricle.

Thus the symptom is one of great importance, and the prognosis serious. The detection of the disease is easy for one who has a moderate acquaintance with the examination of the interior of the eye. The cases themselves are far from infrequent. And the warning given by their occurrence may be practically utilized for the regulation of important business interests. Life itself may often be prolonged by abstinence from exhausting labor, by appropriate relaxation, and the following a suitable regimen.

I am not aware that a series of these cases has ever been followed up, and the result given to the profession. Many difficulties lie in the way of such an undertaking. The ophthalmic specialist differs from the family physician in his ability to keep track of his patients. With many, indeed it may be said with most, a single interview is all that is had. People come from points more or less distant for the purpose of consultation, and on obtaining an opinion return to their own adviser. It is very hard to learn anything relating to their subsequent history.

During the past two years I have gone over all the cases of retinal apoplexy I could find in my records, and endeavored to obtain fresh intelligence in regard to them. By correspondence with relatives and physicians, as well as occasional reference to the obituary columns of the daily press, I have in some instances been enabled to follow them along. Out of ninety I have succeeded in tracing the course of events in only thirty-one. The youngest of these patients was forty-three, the oldest eighty-three, the average age being therefore slightly above sixty-two.

Beginning with the youngest I have arranged a tabular statement as follows:

1. Male. Age forty-three. Very large single hemorrhage, of sudden occurrence. In five weeks vision had wholly returned. Fourteen years later patient alive and well.

2. Male. Age forty-five. Numerous fine hemorrhages scattered over entire fundus. Patient, hitherto engaged in active and engrossing business, gave it up entirely and, from this time forward, led a life of comparative leisure. But the attacks recurred from time to time, and he died of cardiac disease sixteen years later.

3. Female. Age forty-six. In right eye extensive hemorrhage, scattered over macular region, as well as remote parts of fundus. A single splash of blood in other eye. Vision had been for several months observed to be imperfect. Her family physician reported "cardiac hypertrophy, a systolic murmur, and irregular action." Eighteen months later she was seized with convulsions, became unconscious, and died the next day.

4. Female. Age forty-six. Numerous small scattered retinal apoplexies at periphery of fundus in one eye. Vision has been obscure for several months. Examined by Dr. Knight she was found to have well-marked aortic regurgitation. Six months later she had embolism of right hand, two days later of right foot; death supervened in a few days.

5. Female. Age forty-seven. Dark-red spot of blood directly over macula in one eye. Previous

¹ Read before the Massachusetts Medical Society, June 8, 1897, and recommended for publication by the Society.

notes show that, ten years before, two small hemorrhages had been seen near the optic nerve, in the other eye. Dr. Knight examined the heart at that time, and found it normal. The hemorrhages disappeared. Four months after the last attack patient died of apoplexy on a railway train.

6. Male. Age forty-eight. Vision of left eye impaired for three weeks. Numerous small spots of hemorrhage in macular region. Vision one-eighteenth. Sight was ultimately regained, in great measure, and the patient was reported well fourteen years later.

7. Male. Age forty-nine. Very large, fresh hemorrhage just above optic nerve of one eye. Patient much overworked, made to relinquish business and take a journey. Recovery complete, well four years later.

8. Male. Age fifty-six. Blur over right eye for six weeks. Large hemorrhage found near nerve, also numerous smaller ones at periphery of fundus. Some improvement took place, though sight was never completely restored. Died of paralysis two years later.

9. Female. Age fifty-eight. Sudden failure of vision in one eye, numerous fine retinal apoplexies found scattered over fundus. Died of cardiac disease nineteen years later.

10. Male. Age fifty-nine. Small retinal hemorrhage in one eye. Died suddenly of apoplexy, in his state-room on a steamer, about two years later.

11. Female. Age fifty-nine. Vision of one eye suddenly fell off several months ago. Numerous small retinal hemorrhages scattered about macular region. Ten months later died of apoplexy.

12. Male. Age fifty-nine. Within two weeks great failure of vision in each eye. Dilated one pupil and found numerous retinal apoplexies. Other eye similarly affected, as nearly as could be seen through the small pupil. This was in August, and patient died of paralysis the following winter.

13. Male. Age sixty. (Case quoted at commencement of article.) One eye affected for two weeks, enormous number of fine apoplexies. Examined in July; a year from the following February fell in the street with an attack of apoplexy, and died in three days.

14. Female. Age sixty. Failure of sight for two months, due to retinal hemorrhages. Eighteen months later died suddenly of apoplexy.

15. Female. Age sixty-two. Numerous retinal hemorrhages in one eye with corresponding failure of vision, the whole lasting six weeks. Two years later was reported to be in good health, but died of apoplexy seven years afterwards.

This patient was a sister of Case 6.

16. Female. Age sixty-two. Within six weeks rapid failure of vision of each eye. Large hemorrhage in each retina. Patient was six months under observation, and the hemorrhages repeatedly recurred. Is reported to have died of heart disease three years later.

17. Male. Age sixty-three. Several bright splashes of blood near lower edge of optic nerve. Had noticed trouble with eye for a week. This was the middle of March. April 9th a fresh hemorrhage was observed to have taken place. May 8th he fell dead of apoplexy, while sitting at his desk.

18. Male. Age sixty-five. Dimness of one eye observed for a month. A number of small blood spots over macula. His physician wrote concerning

him that he had valvular disease of the heart, apparently at aortic orifice, together with enlargement. Case terminated fatally in less than two months.

19. Male. Age sixty-five. A very large number of small retinal apoplexies in macular region, of recent occurrence. No apparent cause. Vision much impaired, but was subsequently regained, and patient was well and hearty seventeen years later.

20. Male. Age sixty-six. Sudden appearance of spots of retinal apoplexy over macula of one eye. Vision never returned; patient died suddenly of apoplexy three years later.

21. Male. Age sixty-six. In November, 1876, hemorrhages near right optic nerve; in April, 1877, fresh attack; in 1881 the other eye became similarly affected. In August, 1883, died of apoplexy while sitting at the table.

22. Male. Age seventy. In May, 1874, there were several small fresh hemorrhages over left macula. In 1884 patient was in good health, though vision had not returned. In 1890 is reported to have died of "old age."

23. Female. Age seventy. Retinal hemorrhages in each eye, right affected a year, left three weeks. Three weeks later died suddenly of heart disease.

24. Male. Age seventy-two. Vision of one eye greatly impaired for six months. Numerous retinal hemorrhages. General health excellent. Two and a half years later saw him again, no return of vision, health as before. Two years afterwards had an apoplectic seizure, and at the end of two years more died of paralysis.

25. Female. Age seventy-three. One eye only affected, and that within a few days, great failure of vision, hemorrhages scattered over fundus. Patient reported to have cardiac trouble, but no opportunity for examination was offered. Five months later died of heart disease.

26. Male. Age seventy-three. Vision of left eye had been imperfect for a few months. Extensive retinal apoplexies. Two years later had paralysis of the left side, and two years after that died of uremia.

27. Male. Age seventy-four. For two months has observed what he terms a "black ball" before one eye, with much failure of sight. Retinal hemorrhages scattered in all directions. A year later died of apoplexy.

28. Male. Age seventy-six. Right eye affected two weeks, large patches of freshly effused blood in retina. Four years afterwards died of apoplexy.

29. Female. Age seventy-six. Extensive retinal hemorrhages around periphery of left fundus, failure of vision being quite recent. Nine years later died suddenly of heart disease.

30. Male. Age seventy-eight. Four days ago noticed failure of vision in left eye. Numerous bright splashes of blood surround optic nerve entrance. Came from his physician with a diagnosis of cardiac disease, there being a mitral murmur. Died of heart disease a year later.

31. Male. Age eighty-three. Left eye had failed for three years, vision now restricted to distinguishing moving hand. Large spot of effused blood over macula. Sight never returned, but the patient lived on six years, and died finally of inflammation of the bladder.

We have here then, a total of thirty-one persons, between the ages of forty-three and eighty-three, sub-

jects of retinal hemorrhage. Twenty-five of these died after brief illnesses, some indeed with the utmost suddenness. Eleven of this number died of heart disease, fourteen of apoplexy. Five were at last accounts living, their average age being fifty-four, and their cases followed up an average of thirteen years. Another, a man of eighty-three died, six years after he came to me, of an affection of the bladder.

While, therefore, the effusion of blood in the retina cannot be said to uniformly portend danger to life, it has certainly a grave significance, increasing directly with the age of the patient. That it is often overlooked there can be no question. Within a few days I received a visit from a lady aged seventy, who had consulted me fourteen months before. The eyes were then examined separately, both as to vision and ophthalmoscopically, and found to be in the condition that would be expected at her time of life. She saw distant objects with either eye equally well. On the occasion of her second visit she complained that the use of her glasses had of late been attended with difficulty, and she found it impossible to support the continued use of the eyes on near objects. She came supposing that she needed a change of glasses. One eye remained normal, while the vision of the other had fallen off nine-tenths, and there were numerous retinal apoplexies. Of the occurrence of this accident she had not the least idea. Unwilling to alarm her I stated the case to the daughter who accompanied her, gave directions for the treatment of the patient, and wrote to her son, advising a speedy arrangement of any unfinished business matters.

And this is the practical point involved. An early diagnosis, and the consequent recognition of the possibility of sudden death, not only leads to the settlement of business interests that, in the event of an unexpected demise, might seriously suffer; but causes advice to be given that may sensibly prolong the days of the patient. Auscultation, thus suggested, may detect the presence of an hitherto unsuspected cardiac lesion. And in any case suitable diet, leading a regular life, and above all the avoidance of exhausting work or excessive mental activity, have lengthened many a life thus threatened. I cannot doubt but that, if the patient mentioned in the commencement of this paper had followed the advice that was earnestly given him, had retired from his engrossing and exhausting work and taken the vacation he so much needed, a valuable and valued life might have been long preserved to the community. He was a man of powerful physique, and apparently in the prime of his powers, both bodily and mental, when the apoplectic seizure, of which he had full warning, came so suddenly upon him.

These cases must of course be referred back by the specialist to the family physician, to whom indeed their diagnosis ought to be by no means impossible. The patient is generally advanced in years, vision is suddenly impaired, and in a single eye, a general mist or blur being the symptom complained of. Cataract makes its presence more gradually felt, while glaucoma can be recognized by the tension of the eyeball, the enlargement of the pupil, and the characteristic encroachment on the visual field. If there is no reason to suspect either of these diseases, a retinal hemorrhage is, under the circumstances already mentioned, at least probable. To enlarge the pupil, which is ordinarily necessary, a weak solution of scopolamine

may be used, and the degree of familiarity with the ophthalmoscope, which now does or should enter into the training of every physician, enables the observer to make a certain diagnosis.

Medical Progress.

REPORT ON PROGRESS IN THERAPEUTICS.

BY FRANCIS H. WILLIAMS, M.D., BOSTON.

NEW PREPARATIONS OF TUBERCULIN.¹

DR. ROBERT KOCH, in this article, begins by discussing two kinds of immunity—the one against toxins and the other against the bacteria—and goes on to say that the ideal immunity is that which will protect the human body not only against one of the injurious agents but against all of the injurious agents produced by pathogenic micro-organisms; and these considerations play a great rôle in tuberculosis. All attempts made to secure in any numbers the absorption of unchanged living or even dead tubercle bacilli by the subcutaneous tissue, by the peritoneal cavity or by the circulation, failed; and as it was then proved that bacilli in an unchanged state could not be used for purposes of immunization, an endeavor was made to render the bacilli absorbable by some chemical attack, and to this end they were treated with dilute mineral acids or with strong alkalies under boiling heat. As this also failed of its purpose, the absorbable constituents were extracted from a mass of tubercle bacilli in order to use them for purposes of immunization; and experimenting with glycerine extraction led to the discovery of tuberculin.

Tuberculin has the valuable property of producing a characteristic reaction in animals and man affected with tuberculosis, when introduced subcutaneously in very small quantities, and may be utilized in the recognition of tuberculosis in the earliest stages. The fear that, in consequence of the reaction, the tubercle bacilli would be rendered mobile and would then be transmitted to healthy animals, has been shown in many thousands of tuberculin injections, made upon cattle as a test, to be perfectly groundless.

The further use of tuberculin consists in its employment in the treatment of tuberculosis. As an unmistakable improvement in the tuberculous process occurs after every reaction produced by tuberculin, it would seem proper to continue the reaction as long as any improvement shows itself. But this improvement cannot be indefinitely continued, as the reaction against tuberculin is gradually lost, and with it, of course, the effect of the tuberculin; so that, finally, there comes a period of perfect immunization against the tuberculin, and this period may last for several months. This immunization has no effect upon the tubercle bacilli themselves, it is a pure toxic immunity, and not a bacterial immunity. Unfortunately, the reaction against tuberculin is very often lost before there is anything like a perfect cure of the disease, and a relapse sets in which must again be treated with tuberculin reactions so soon as the capability of reaction is established. Still, treated in this way, with the necessary skill and patience, a cure, or at least very great

¹ Deutsche med. Woch., April 1, 1897, translation in Cincinnati Lancet-Clinic, April 24, 1897.

improvement, may be secured, if not in all, at least in very many cases of uncomplicated tuberculosis.

Dr. Koch goes on to say that tuberculin would, therefore, be the best agent for the treatment of tuberculosis were it not that he has in the mean time succeeded in securing from cultures of the tubercle bacilli preparations which immunize the body against the tubercle bacilli themselves. The writer then describes what he calls, for the sake of brevity, the T A preparation (T for tuberculin; A, because the preparation is an alkaline extract). Experiments with T A showed that very small doses produced quite similar reactions to those obtained by tuberculin, but they were of longer duration, and the capability of reaction lasted longer than in the case of tuberculin; but the chief advantage was that the results obtained were more constant, so that relapses were fewer and farther apart. This preparation was abandoned because abscesses developed under pretty high doses at the point of injection; these abscesses were perfectly sterile and could have only been produced by the dead tubercle bacilli from which the T A preparation was not perfectly free.

Experiments made with T A led the writer to understand that under no circumstances could tubercle bacilli be absorbed in the undestroyed state, but this desired absorption might be obtained by breaking them up mechanically; and he was strengthened in this idea by observations which he had made in the chemical treatment of tubercle bacilli. Tubercle bacilli contain two peculiar chemical bodies, which both belong to the group of unsaturated fatty acids. One of the fatty acids is soluble in dilute alcohol and is easily saponified by soda lye; the other is dissolved only in boiling absolute alcohol or ether, and is hardly at all saponified. Both take on the so-called tubercle bacilli stain, that is, they are colored intensely red by carbol fuchsin, and keep this color after treatment with dilute nitric acid and with alcohol. Now, as in this treatment the first of the two fatty acids is dissolved in alcohol and withdrawn from among the microscopic objects, there remains in this coloring treatment, when it is applied to the tubercle bacilli, only the second fatty acid, insoluble in cold alcohol. This acid fixes the stain, and is thus the carrier of the color peculiar to tubercle bacilli. The fatty acid may be slowly driven out of the tubercle bacilli by hot soda lye, and the process of separation may be easily followed with the help of the microscope, in which it is seen that the fatty acid escapes from the bacillus in the form of stainable drops, which flow together to constitute larger drops, while the bacilli at first still maintain their form but have lost the specific coloring of tubercle bacilli, and have only that which belongs to other bacteria. These fatty acids form, as the microscopic picture of stained bacilli shows, a connected layer in the body of the bacillus; they protect it from attacks from without and are the cause of its slow absorption. The point was, how to destroy this protective envelope in order to make the tubercle bacilli absorbable. The first experiments in this direction failed but finally success came. Well-dried cultures were rubbed thoroughly in an agate mortar with an agate pestle until there was a diminution in the number of colorable tubercle bacilli, and at last only a few tubercle bacilli remained, and these were removed by placing the substance in distilled water and centrifuging it; the fluid could then be separated into

a perfectly clear transparent layer which contained no tubercle bacilli, and a solid, muddy sediment. This sediment was again dried, pulverized and centrifuged as before; and again there was a clear upper layer and the solid deposit. This process can be repeated until the whole mass of tubercle-bacillus culture is converted into a series of perfectly clear liquids.

Experiments made upon animals, and later upon man, were convincing that the preparation thus obtained was entirely absorbable and never produced abscesses if it had been thoroughly centrifuged and contained no colorable bacilli. It was soon seen that the first fluid only, differed essentially from those subsequently obtained in the experiment above described. The upper layer which resulted from the first centrifuging is designated as Tuberculin O (the O stands for *obere*, upper), or T O; while the rest, obtained after the first centrifuging, received the name T R (R for rest).

The conduct of T R in the presence of glycerine shows that it contains essentially the constituents of tubercle bacilli, which are insoluble in glycerine and which in a glycerine extract remain behind; while T O includes the parts soluble in glycerine. The test of the two preparations in animals and man coincides with this view. The T O approaches very nearly in its properties to the common tuberculin, and shows an effect almost exactly like that of T A (alkaline extract, already alluded to), except that no abscess formation is to be feared in the case of T O; but it has very little immunizing property.

The T R, on the contrary, has decided immunizing properties. It produces reactions in the tuberculous patient when too large a dose is used, but the effect is entirely independent of these reactions. While reactions must be obtained in order to accomplish curative effects with common tuberculin as well as with T A and T O, the endeavor was made, in the use of T R, to avoid reaction as much as possible and to make the patient insusceptible by gradual increase of the dose, as rapidly as it could be done, it is true, but at the same time to avoid as far as possible the larger doses; that is, endeavor was made to immunize the patient against T R and the tubercle bacilli. An individual who is immunized against T R no longer reacts to large doses of the common tuberculin, or of T O; in other words, he is immunized against all the constituents of the tubercle bacilli. Dr. Koch states that there can be no doubt of this property of the T R, as he has proved the correctness of the observation in a large number of cases.

The T R preparation, to be effective, must be made from extremely virulent cultures (tubercle bacilli are not so uniformly virulent as has been assumed); the less virulent furnish less effective or entirely ineffective preparations. The cultures should not be too old; in fact, they should be made as fresh as possible, that is, immediately after they have become perfectly dry. All chemical intervention should be avoided, as the T R appears to be very sensitive. For the same reason the cultures, as well as the preparations, should be protected from the light. The T O must be carefully separated from the T R, or there remains in the latter a more or less large quantity of T O, the injection of which produces undesirable reactions.

Dr. Koch discusses the danger to the private individual in making T R, and considers it for this reason

out of the question that it should be done with the hands in any large quantity; it should be made by machinery.

Injections of T R, as with tuberculin, are made in the back by means of a syringe which is easily sterilized. The fluid contains, to the cubic centimetre, ten milligrammes solid substance, and is diluted to the proper dose by the addition of the physiological salt solution. One five-hundredth of a milligramme should be used at first; and this dose is so small that it only in rare cases produces any reaction; but should this be the case, the dose may be still further diluted. Injections are made about every second day, and with such a slow increase of the dose that any marked elevation of temperature, even half a degree, is as much as possible avoided. Any elevation caused by the injections must disappear before the injection is repeated. As a rule, the dose has been increased to twenty milligrammes, and has then been stopped if no reaction followed, or injections have been made only after longer intervals.

If animals are to be immunized, as much as can well be absorbed should be used in the beginning—for a guinea-pig, for instance, two to three milligrammes, and correspondingly more for larger animals. In the case of tuberculous animals a much smaller amount must be used at the start, as even a dose of two milligrammes may under certain circumstances prove fatal. In the immunization of sound, and the treatment of diseased animals, everything depends upon using the largest possible dose that can be easily absorbed. This condition being satisfied, a large number of guinea-pigs were immunized so that they could endure repeated inoculations with virulent cultures without becoming infected. The point of inoculation disappeared without leaving any trace, and the neighboring inguinal glands remained in some cases for months entirely unaffected. In others they were enlarged, but without any visible tuberculous change. Tubercle bacilli could not be found in them.

In a certain number of animals the immunization was not complete at the time of the first inoculation. In these cases the point of inoculation had healed, but the inguinal glands had become caseous. The internal organs, on the other hand, were free from tuberculosis, while the control animals showed far advanced general tuberculosis of the lungs, spleen and liver.

Experiments made with tuberculous guinea-pigs gave the impression that full immunization sets in in two or three weeks after the use of the larger doses. A cure in tuberculous guinea-pigs (animals in whom the disease runs a very rapid course) may therefore take place only when the treatment is begun early, as early as one or two weeks after the infection with tuberculosis.

This rule holds good also for tuberculous human beings, whose treatment must not be begun too late. Such small doses must be given at first as to necessarily exclude any distinct immunization in the beginning, it is only when larger doses are reached, one-half to one milligramme, that the unmistakable effects of immunization are observed. A patient, then, who has but a few months to live, cannot expect any help from the use of the remedy, and it will be of little use to treat patients who suffer chiefly from secondary infections.

The T R preparation has been used in a tolerably large number of proper cases, and especially in lupus.

Three cases showed more improvement than is obtained by common tuberculin or by the T A preparation. The word *cure* is not used, as a sufficiently long time has not yet elapsed.

In phthisical patients the well-known violent reaction of tuberculin, with the temporary infiltration in the diseased lung tissue, was absent. A slight increase in the râles, which speedily disappeared, was, as a rule, the only local symptom attending the use of the T R preparation. The sputum diminished after a few injections, and there was a corresponding diminution in the number of tubercle bacilli, which soon disappeared altogether. The râles likewise disappeared, and the region of dullness diminished. The patients began to gain in weight from the beginning, and made essential gains by the end of the treatment. The zigzag line of the temperature curve, in cases which showed a daily variation of one degree Centigrade, or more, straightened itself by degrees and gradually reached the normal.

Dr. Koch closes by saying that the method which he has employed in the use of T R, namely, a gradual increase from the smallest subcutaneous doses up to about twenty milligrammes, may not be the best. Other methods, perhaps combinations with T R, or with serum preparations obtained by means of T O or T R, may lead more quickly and surely to the desired end; but he believes that further improvements in the preparations themselves are not to be expected.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

JAMES G. MUMFORD, M.D., SECRETARY.

REGULAR meeting Monday, February 22, 1897, Dr. A. L. MASON in the chair.

DR. GEORGE W. GAY reported a case of

LIGATURE OF THE INNOMINATE ARTERY.¹

DR. MASON inquired how many instances there are where patients have survived any considerable time, say, five years.

DR. GAY: Dr. Burrell gives a list of 29 cases, including his own. Mine would be the 30th unless others have been reported in the meantime of which I have no knowledge. Ten of these cases lived over one month. Three, besides his own, are reported as recoveries. One died at the end of ten years of hemorrhage from the original aneurism; Dr. Burrell's patient died in 104 days of arterio-sclerosis, and an enlarged and dilated heart. Two others are reported well at the end of six weeks; another died in 68 days of hemorrhage. The remainder of the ten died in periods varying from 33 to 43 days. The case herein reported makes 11 out of 30, that have lived more than a month after the operation.

A HALF-CENTURY OF MEDICAL JOURNALISM.—The *New Orleans Medical and Surgical Journal* is celebrating its semi-centennial. It was established in 1844, but suspended publication during the years of the Civil War.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

FOURTEENTH ANNUAL MEETING, WASHINGTON, D. C.,
MAY 4, 5 AND 6, 1897.

The following officers were elected for 1898: President, Dr. Edward O. Otis, of Boston. Vice-Presidents, Dr. Beverley Robinson, of New York; Dr. C. F. McGahan, of Aiken, S. C. Secretary and Treasurer, Dr. Guy Hinsdale, of Philadelphia. Council: Dr. R. G. Curtin, Philadelphia; Dr. I. H. Platt, Lakewood; Dr. S. E. Solly, Colorado Springs; Dr. J. B. Walker, Philadelphia; Dr. E. Fletcher Ingals, Chicago.

The President, Dr. E. FLETCHER INGALS, of Chicago, after reciting briefly the history of the Association since its organization in 1884, called attention to the great increase in our knowledge of the climatological possibilities in the United States, and urged the members to extend their studies to the effect of climate on various other diseases, in addition to those of the respiratory and circulatory organs. He briefly cited several cases illustrative of the benefits to be derived from various antiseptics and from an antiseptic atmosphere, and urged upon the profession the inutility of sending patients at all advanced in the disease away from home excepting under the most favorable circumstances. The paper closed with the following conclusions:

In addition to tonics, supporting or anodyne remedies, various antiseptics appear to possess great value in relieving pulmonary tuberculosis, but in order to get good effects it is imperative that the system be as nearly saturated with them as possible. They should be given at first in small doses but the amount should be steadily increased until the maximum dose is obtained; care being always taken not to disturb the digestive organs. For example, with the oil of cloves we may begin with five drops given in capsules from three to five times daily after each meal and in the middle of the forenoon and middle of the afternoon, the medicine always to be followed by a glass of milk. The second day the dose should be six drops, the third seven, and so on until a dose of twenty-five or thirty drops is given each time.

Creosote can seldom be given in sufficient quantities to have any material effect because of the disturbance of the digestive organs which it is liable to cause and because of its coagulating all albuminoids. The same may be said of carbolic acid.

The carbonate of creosote is much more bland, and may be given in doses of from five to sixty drops after each meal with the greatest benefit.

Guaiacol may be given in much the same way as the oil of cloves, though in somewhat smaller doses; but it is usually less easily borne than the carbonate of creosote or oil of cloves, and often cannot be tolerated in sufficient quantities. The carbonate of guaiacol may be used in much the same way as guaiacol itself, but most patients seem unable to take it in sufficient doses.

Iodine may be used as recommended by Shurly, with undoubted benefit, but it causes considerable pain and is open to the objection that it necessitates too constant attendance of the physician. It may also be used advantageously as an inhalant.

Patients should not be sent from home unless their financial and social position is such as to render the journey and sojourn easy and agreeable.

In the first stage of the disease patients should, as a

rule, go to a high altitude where the atmosphere is as warm as practicable. In the second stage they should be sent to a medium altitude. In the third stage, if sent anywhere, it should be to a low altitude and in most instances to a dry atmosphere.

When sojourning in a favorable climate, the patient should be out of doors as much as practicable during the pleasant portion of the day, and should avoid excessive heat, excessive cold and unusual fatigue.

Patients who have been improving under any course of medication should not discontinue it upon going to a different climate; and however valuable any remedy may appear, it should not be continued if it becomes clear that it is deranging the digestion.

Of anodynes to check cough, hyoscyamus, camphor, cannabis indica, stramonium and conium are of most value because they can generally be taken in sufficient quantities without disturbing the digestion, whereas opiates are usually deleterious in whatever form they may be employed.

The majority of patients sent from home in the latter stages of pulmonary tuberculosis are injured by the journey and their lives correspondingly shortened, though in a small percentage very great benefit is obtained.

DR. S. E. SOLLY, of Colorado Springs, said that the great desideratum as to resorts was to get at facts and not opinions. He had encountered great difficulty in this respect in the preparation of his work on medical climatology. We want reliable data as to the nature of the soil, the slope of the ground, and many other features not always embraced in meteorological reports. As to the use of antiseptics, Dr. Solly said that in the present instance it is one of those rare occasions in which he cannot agree with the President. His own practice was to ascertain, when new patients presented themselves, whether the oil of cloves or the creosote or other antiseptic was doing well; if so, he continued it, on the principle that it was well to have something definite for the patient to do—some rallying point for good moral effect; as to most of the forms of specific medication, he believed that they exert their beneficial influence on the principle of "omne ignatum pro magnifico."

DR. ROBERT H. BABCOCK, of Chicago, submitted

A BRIEF CONSIDERATION OF SOME POINTS IN THE
MANAGEMENT OF CONSUMPTION.

As the author's aim was to elicit discussion, his paper was suggestive. He agreed with Finlayson and others that the consumptive's temperature is not febrile until it reaches 101.3° F., and only then requires treatment. He first advises rest in the open air and regulation of the diet. If this does not reduce the temperature, he advises careful sponging or the use of small doses (one and a half to three grains) of antifebrine or some other non-depressing antipyretic an hour before meals, as suggested by Detweiler, for the purpose of promoting the secretion of free hydrochloric acid during digestion, it being absent during fever. Sweating he combats with picROTOXIN and camphoric acid. Diarrhea is considered due to intestinal ulceration less often than is generally supposed, but rather to intestinal fermentation, and is treated with intestinal antiseptics rather than opium and astringents.

He inquired if laryngeal tuberculosis did not contraindicate high altitudes, and wished to learn from Colorado members why patients were often retained at

that high altitude after having developed laryngeal symptoms.

It is his belief that patients having recovered in high altitudes should not return to reside at their former homes in the East, although he has known individuals to do so without apparent harm. He wished to learn if the members did not consider such return unsafe and likely to bring on a fresh outbreak of the disease.

DR. CHARLES F. GARDINER, of Colorado Springs, read a paper on

THE DANGERS OF TUBERCULAR INFECTION AND THEIR PARTIAL ARREST BY CLIMATIC INFLUENCES.

The paper gave the result of an elaborate bacteriological study. Dr. Gardiner said that in reviewing the evidence of partial arrest of tubercular infection by climatic influence, all data of a general character have to be taken with great caution. The impression that in the arid or elevated regions of the world, consumption from being so rarely seen, is not communicated from the sick to the well, is not at all proved from such imperfect and unreliable statistics as have generally been brought forward. The immunizing power apparently possessed by a climate may be really due to manner of life, such as isolation and the like, day and night in the open air; or selected lives, such as the early settlers of any country live, who, to cope with its hardships, have of necessity to be the strongest.

It is, therefore, only after a country has been settled some little time that indoor industries, overcrowding and the general unsanitary environment of civilization, exert their full action, and that any reliable data concerning climatic arrest of infection, can with real accuracy be computed; as no experiment is accurate unless conditions are equal, or nearly so. Conditions are now, however, favorable for comparison, as the dry and elevated regions of almost the entire world have populous cities, whose inhabitants lead indoor lives, and whose environment closely approaches that of dwellers in the dense civilized centres from which our statistics have for years back been taken; so that at the present day, comparative statistics of tuberculosis, collected with care, show the relation between a seaboard town and one at an elevation of six thousand feet with a degree of accuracy and truth that leaves very little to be desired in a collection of scientific data.

In regard, therefore, to infection, the fact that so many consumptives are brought into such close contact with well people in Colorado Springs seems, no doubt, a clear evidence that a risk in proportion to the exposure must logically result. Theoretically considered, such an opinion, based on well-known laws and statistics of other cities, would be safe to follow, other things being equal; but other things are not equal. A factor of six thousand feet altitude comes in, and six thousand feet exerts a very strong and important action in limiting the extension of tuberculosis in Colorado Springs. This is, also, not an isolated instance; Colorado Springs is not alone in having such a low record. The low mortality from non-imported consumption contracted in Colorado Springs has its counterpart in other cities in this elevated dry belt. Even Denver, a city of 150,000 inhabitants, with tall buildings shutting out the sunlight, industrial occupations which are so conducive to tubercular increase, and, in addition, a large proportion of consump-

tive invalids scattered among its other inhabitants, had, as shown by the reports, only 64 deaths from non-imported consumption (less than half of a death to the thousand) in 1896. The average city would show 450 deaths per year to 150,000 inhabitants, without the climatic factor possessed by Denver. Dr. Gardiner sent out in April fifty circular letters to doctors in Utah, Arizona, Wyoming, New Mexico and Colorado, asking the number of cases seen or heard of by them, and the number of years each had practised in his present locality. In this way he took in fairly well the dry belt, some of which was at one thousand feet altitude only. The result from answers received was 203 years' observation in practice and 130 cases of non-imported phthisis reported — fully 80 per cent. of which were either from Salt Lake City, in native Mexicans in New Mexico, or in an altitude below three thousand feet. This compares well with results observed in other parts of the world.

The climatic influence that favors recovery from consumption, is no doubt composed of many factors. Very briefly they can be stated as follows: The tubercular germ, distributed as dust, is much more likely to lose its virulence exposed in a climate where the sunshine is so constantly present and the air so thin. The air cells of the average lungs are more used, more brought into healthy action at an altitude of six thousand feet; the increase, as told by the spirometer and by chest measurements, is very marked in newcomers to the dry elevated climates; and it follows that organs so exercised, both by increased ventilation and increased blood-supply, do not as readily become a suitable medium for the growth of tubercle bacilli.

DR. S. G. BONNEY, of Denver, detailed his
OBSERVATIONS UPON PULMONARY TUBERCULOSIS IN COLORADO.

He presented an analysis of 200 recorded cases selected from private practice during a period of two years. He discussed these cases with reference to the probable prognosis at time of arrival, and in stating the results he made a classification according to the physical signs and general condition. Then followed a brief summary of statistical and general observations relative to age, sex, distribution, previous environment, inherited predisposition; the extent and character of the tubercular involvement; the method of onset; the relation of climate to hemorrhagic cases; the relation of climate to cases exhibiting greater or less degree of functional nervous disturbance; the relation of climate to bronchial irritation. He discussed the complications, with special reference to tubercular laryngitis, and closed with general observations as to management.

AËRO-THERAPEUTICS AND HYDRO-THERAPEUTICS IN THE TREATMENT AND PREVENTION OF PULMONARY TUBERCULOSIS.

DR. S. A. KNOPF, of New York, in a paper with this title, spoke of preventive medicine as the medicine of the present. While hoping that preventive inoculation and sero-therapy would be the ultimate treatment for all acute diseases, he expressed doubts as to the discovery of a serum or toxin which would cure pulmonary tuberculosis when it had already worked its destructive process. He recommended continued research to combat the association of microbes manifested by acute exacerbation, and stated that his

own work in that direction with antiseptic serum had been encouraging.

In describing the anatomical, physiological and pathological peculiarities of the individual predisposed to pulmonary tuberculosis, he pointed out the remedies to overcome the insufficient air-supply to the respiratory organs, and the abnormally increased sensibility of the general, and especially the cutaneous, system to the slightest changes of temperature. He showed that the preventive treatment of consumption should begin with the child *in utero*, and be kept up throughout life. Dr. Knopf completed his paper with a description of a thorough system of aëro- and hydro-therapeutics.

THE SALICYLATE TREATMENT OF HEMOPTYSIS.

DR. THOMAS J. MAYS, of Philadelphia, presented a paper with this title. He believes that such drugs as gallic acid, tannin, ergot, geranium, hamamelis, digitalis, turpentine, etc., although supposed to be sheet-anchors, are consummate failures in the treatment of many cases of hemoptysis. This, the author thinks, is due to the fact that they do not fill the gap which exists between what they can do and what we expect them to do. He holds that in many cases the arresting of bleeding from the lungs does not rest on our therapeutic agent's power to constrict the pulmonary capillaries, but on their influence in removing that toxic condition which weakens the wall of the blood-vessel and makes it permeable to its contents. Such a toxin he believes the rheumatic poison to be, which, he thinks, is more frequently engaged in bringing about hemoptysis than is usually suspected. At any rate, practical experience demonstrates that many a case of blood-spitting which is uninfluenced by any other internal remedy, yields to the salicylates of soda and cinchonidia, very readily. Several typical cases illustrating the utility of these drugs were recorded.

DR. JOHN MADISON TAYLOR, of Philadelphia, read a paper on

THE EFFECT OF CLIMATE UPON NEURASTHENIA AND MELANCHOLIA.

Dr. Taylor's conclusions are: (1) that change of climate is of relative insignificance in the treatment of neurasthenic states, although changes of situation quite frequently are of more or less importance; (2) that the most important element of change has to do with environment, including, not only change of place but of persons and things; (3) that it is important to outline what constitutes the essential points in this change of environment, so that the average practitioner may keep in mind such imperative conditions and modifications as the varying needs of the individual, his domestic and financial status, make necessary.

He discussed briefly the climatic conditions which make or mar success, and related his own experience, making special reference to the undesirability of radical changes inconsistent with the customary life of a patient, such as reversing the seasons, sending a dweller in the cold North to spend a winter in the tropical South. He noted the distinct harm wrought upon a highly sensitive nervous organization thrown out of balance by a prolonged residence on the seacoast or high mountain regions. And, lastly, he called special attention to the hurtfulness of rushing about from place to place in obedience to morbid impulses, the outcome of agitation due to disease.

DR. SANGER BROWN, of Chicago, presented a paper on

DISEASES OF THE NERVOUS SYSTEM AFFECTED BY CLIMATE.

Benefits from a temporary change of climate are due:

(1) To incidental influences, such as relief from responsibility, change of scene, an outdoor life and regular habits.

(2) To the influence of the climate in the promotion of the general health.

(3) To the direct effect of the climate upon the disease itself, as the healing influence upon the lungs popularly attributed to inhalation of the atmosphere of certain districts.

The first two are of much more importance than the last, even in pulmonary tuberculosis; for, unless they act, the disease invariably progresses. Their effects may be quite generally referred to the nervous system.

In general, individuals in good health but of the nervous temperament—natural instability of the nervous system—do badly in a high altitude; more particularly, however, in conditions where the nervous equilibrium is much reduced, as is often the case in the victims of overwork, in consumption, and in woman at the climacteric period, a very high altitude is not well borne. Tinnitus, insomnia, mental confusion, a tormenting sense of nervous tension, restlessness and apprehension are some of the most conspicuous symptoms in these cases. An inland dweller is sometimes affected in a similar way by sea air, but the symptoms are very much less in frequency and degree; indeed, I have not known tinnitus to be so caused.

A cold and sunny climate, with an altitude not above three thousand feet, is the one best suited to the restoration of a debilitated nervous system, no matter hardly to what cause this may be due. Providing the patient has enough nervous energy left to enable him to react, and if the kidneys are sound, it is surprising how slight the danger is in sending even a very frail invalid to a cold climate and keeping him much out of doors, if reasonable precautions are taken. I mean by a cold climate, one in winter in which the temperature ranges much of the time from 10° to 0°, as Ottawa, Ont., St. Paul or Winnipeg, and where in the summer it falls very frequently at night to from 36° to 46° F.

Too much is not to be expected from patients far past middle life, for the conditions of success depend upon the existence of latent nervous energy which the comparatively low temperature liberates. In the winter, at least, two or three months' residence in such a climate is usually a sufficient time to test its efficacy in a given case. Elderly people very often, and patients of any age sometimes, do better in a mild climate, like that of Central Texas or Redlands, Cal. Organic diseases of the nervous system are not directly affected by climate.

To briefly recapitulate: in debilitated states of the nervous system attended with such disturbances of function as simple melancholia, neurasthenia, neuralgia, insomnia, neuroses incident to the menopause and hysteria, a high altitude and the sea-shore are contra-indicated; and while generally in such cases a clear, cold climate is most beneficial, a few cases do better in a mild inland climate. After a certain degree of improvement has taken place, this may frequently be advanced by sea or even mountain air.

(To be continued.)

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JULY 22, 1897.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal 283 Washington Street, Boston.

RECENT FOREIGN LITERATURE ON APPENDICITIS.

THE subject of Appendicitis has been attracting anew the attention of physicians and surgeons on the continent of Europe. At the meeting of the German Society of Surgery, held April 21st, the importance of early surgical intervention was emphasized. This was also, in part, the consensus of the discussion before the Société de Médecine et de Chirurgie Pratique at a recent meeting. The French medical mind has in the past been inclined to conservatism, and it has been regarded as good practice to wait a week or longer—even in severe cases—in the hope that this perityphlitic abscess might be well walled in from the abdominal cavity.

Paul Reynier, at the above-mentioned meeting, advocated this procedure. In the immense majority of cases intervention should be tardy, and by this he meant, put off till some time between the fifth and ninth day. He would except appendicitis in young children, which has little tendency to be attended with neo-membranous formation and walling in of the suppuration. His experience with appendicitis in adults leads him to call especial attention to the proneness of this disease to be followed by a peritonitis which is distinctly localized. Out of forty cases, he has seen but three deaths from general peritonitis. There is, therefore, a great gain in waiting till the peritonitis is localized in the cecal region, and adhesions are formed protecting the rest of the peritoneal cavity. In exceptional cases of the fulminant character, laparotomy should be performed at once, as soon as the diagnosis is made.

Dr. Louis Beurnier had little faith in the medical treatment of appendicitis. Every case of appendicitis is "of the province of the surgeon," and should be under the constant care and scrutiny of the surgeon, in readiness for an operation.¹ In many cases it may

be expedient to wait "till the acute period of the onset is passed, till the general condition is improved by injections of caffeine, and the local state is ameliorated by applications of ice," but the laparotomy should only in exceptional cases be deferred beyond the third or fourth day. He insists on the necessity of a free incision, prolonged well upward, so as to give plenty of room for exploration. If the pus does not flow by gentle manœuvres, use care in exploring with the finger so as not to break down adhesions. It is often better to leave the appendix *in situ*.

Dr. F. Verchère contributed to the same society a brilliant paper, in which he stated the view that there are two types of appendicitis, both having a different pathogeny and different clinical tableaux. There is no difficulty in accepting the two types; but is not the malignant form an aggravation of the simple benign type, due to the same microbes and toxins, only intensified by causes not yet well understood? We know that one type is relatively benign, characterized by a phlegmon of the right iliac fossa; this phlegmon may go on to suppuration, or it may remain "sero-fibrinous" and end in resolution. The sequels of the appendicitis may be those of an ordinary abscess opening externally or especially dangerous only if it bursts into the peritoneal cavity. Cases of this type do not show a marked degree of infection. The phagocytes of the individual affected, early display their protective activity in a sufficient degree to get the upper-hand of their bacterial adversaries, walling away from the abdominal cavity the seat of infection; and only a localized focus of suppuration attests the mischief wrought in the *vase close* of an occluded appendix.

The malignant type of appendicitis is appropriately called by Verchère "intestinal-peritoneal septicemia." These cases are generally fatal, though a small percentage are saved by an early operation. Here there is intensification of the virus owing to favorable culture conditions in the "closed receptacle" and rapid absorption of toxins with generalization of the inflammation to the peritoneum and a speedy septicemic break-down. There may be but little localization of the mischief, and from beginning to end no suppuration.

Paul Reclus writes² on "The Pathogeny of Appendicitis." His paper deserves more notice than the limits of this article will allow. He shows that the *vase close* theory is more or less applicable to the disorder following all kinds of appendicitis; for when an inflammation is once started in that diverticulum, there is, owing to its peculiar shape and situation, the greatest tendency to stagnation of the contents, thus offering the very best culture field to bacteria of the intestine, notably the streptococcus and coli bacillus. But many cases of appendicitis do not start in the appendix, but are propagated from an enteritis of the colon and cecum, and it has been of late proved that appendicitis sometimes originates from general causes, as infectious fevers. But whatever cause may have been operative, "the structure of the appendix, its cana-

¹ Bull. et Mem. de la Soc. de Méd. et de Chirurgie Pratique, fasc. iii, 1897.

² Semaine Médicale, June 23, 1897.

lular form, its nature as a diverticulum make it the equivalent of a blind natural fistula where microbes stagnate and with exaltation of their virulence, invade its walls, cause ulceration and perforation, and easily by propinquity excite grave peritonitis."

It is interesting to note that the differences of opinion with regard to early operation, which were and are still mooted questions in this country, are dividing surgical opinion among our foreign *confrères*.

The trend of the best surgical opinion, abroad as well as at home, appears to be in favor of early operation in the fulminating cases; while, in a very large class of cases, namely, those of more moderate severity, surgeons are learning to wait until the height of the attack is passed, when the abscess, if it forms, can be opened with comparative safety, and the appendix, if it can be reached without danger of rupturing adhesions and infecting the peritoneum, removed. After the patient has recovered from this operation, the appendix may, if not obliterated, and still causing trouble, be removed with comparative safety.

There is also a large class of cases in which an exudate, although comparatively large in an acute attack, is entirely absorbed by natural processes, and no further attack may follow, or the appendix may be removed by the comparatively safe internal operation.

MEDICAL NOTES.

HONORS TO DR. PRUDDEN.—The degree of LL.D. has been conferred by Yale University on Dr. T. Mitchell Prudden, Professor of Pathology in Columbia University.

DEATH OF PROFESSOR FRESENIUS.—Professor Carl Remigius Fresenius, the great chemist, died at Wiesbaden, June 10th, of apoplexy. He was born at Frankfort-on-the-Main in 1818. He was made professor of chemistry at the Institute of Wiesbaden, and was the author of several works on chemistry which have a world-wide reputation.

BEDS FOR SICK AMERICANS IN LONDON.—As a memorial of the Queen's Diamond Jubilee the Americans residing in England have endowed a bed in perpetuity in each of the five leading London hospitals, each bed being endowed with the sum of £1,000. The beds will be especially for the use of Americans, but other patients may be received if all the Americans are well.

Muzzling in Ireland.—Ireland has been subjected to the dog-muzzling order, the Irish Privy Council having been moved by Mr. Walter Long, M.P., to make the order, and this notwithstanding the fact that there is no rabies on the island, and no danger of any at present. It also appears that the importation of dogs is to be prohibited after September 18th.

DEATHS UNDER CHLOROFORM.—The usual number of deaths under chloroform anesthesia continues

to be reported in the *British Medical Journal*. A recent case, which occurred on May 17th at the Derbyshire Royal Infirmary, was that of a child who was to be operated for empyema, but died under the anesthetic before the operation could be begun. Artificial respiration and stimulants were of no avail.

POST-GRADUATE FACILITIES IN RUSSIA.—There are facilities for post-graduate study at the ten Russian universities and at the Army Medical Academy at St. Petersburg. Courses on various special subjects, varying from one to three months, are held, and the fee charged is a small one, averaging about \$2.50. There are abundant opportunities for graduates desiring to do original scientific work in the laboratories of the universities and hospitals.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, July 14, 1897, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 41, scarlet fever 15, typhoid fever 6. For the week ending July 21st the following cases were reported: diphtheria 44, scarlet fever 18, measles 23, typhoid fever 3.

A CENTENARIAN'S BIRTHDAY.—Mrs. Nancy Wood Kilburn, the oldest person in Worcester, celebrated her one hundred and second birthday anniversary on July 12th. Mrs. Kilburn was born in Westminster, July 12, 1795. She has living four children, eleven grandchildren and seven great-grandchildren.

VALUABLE BEQUESTS TO THE BOSTON MEDICAL LIBRARY.—The Boston Medical Library has received by bequest the medical libraries of the late Drs. Edward Wigglesworth, of Boston, and William G. Wheeler, of Chelsea. The former is composed almost entirely of books and periodicals on dermatology, and contains nearly everything published on this subject up to a short time before the death of Dr. Wigglesworth. The latter consists of books by early American writers, standard medical works, files of valuable periodicals and an excellent collection of books and monographs on obstetrics and gynecology. These gifts will greatly strengthen several departments of the library and add to its usefulness.

NEW YORK.

REPORT OF THE MAYOR'S COMMISSION ON SMALL PARKS.—At the last meeting of the Board of Education for the season, held July 14th, the report of the Mayor's Commission on Small Parks was presented. After calling attention to the great importance of the work for which it was appointed, the report stated that in the opinion of the committee one of the most practical ways of obtaining playgrounds for children in the congested tenement districts of the city was to secure the co-operation of the board in throwing open for public playgrounds the grounds around school-houses, and that there were seventeen school-houses in the district referred to with grounds available

for the purpose. In planning new schools the board was asked to select sites with reference to the suggestion made by the committee. It was also suggested that roof-gardens on the school-buildings might help to solve the difficult question of providing the tenement districts with sufficient breathing-places, than which nothing was more important for the health and character of the children.

THE SEATING OF SCHOOL-CHILDREN.—At this same meeting of the Board of Education the seating capacity of school-rooms was limited by the adoption of an amendment to the by-laws providing that in all buildings hereafter erected, primary rooms shall seat only fifty pupils each, and grammar grades only forty pupils; moreover, that in the primary rooms there shall be at least ten square feet of floor space for each pupil, and in the grammar grades, at least twelve square feet.

APPOINTMENT OF OCULISTS.—Drs. Charles S. Bull, Henry D. Noyes and A. Grünig, have been appointed expert oculists for the examination of public-school children.

APPOINTMENT OF ATTORNEYS FOR STATE LUNATIC HOSPITALS.—Up to the present time all the legal work in connection with the State Hospitals for the Insane has been carried on by the Attorney-General's Department, but at the last session of the Legislature a bill was passed providing for the appointment of a special attorney for each hospital in the State, at an annual salary of \$1,200; and something of a scandal has now been created by the announcement that the State Commission in Lunacy in making their new appointments have selected members of the Legislature who were chiefly instrumental in securing the passage of the bill.

Miscellany.

YELLOW FEVER AND THE BACILLUS ICTEROIDES.

A LECTURE on this subject by Prof. G. Sanarelli, director of the Institute of Experimental Hygiene in the University of Montevideo, a translation of which is published in the *British Medical Journal* of July 3d, cannot, in view of the fact that Professor Sanarelli is generally credited with the discovery of the bacillus of yellow fever, fail to be of great interest. The clinical, anatomical and bacteriological researches, the results of which are embodied in this lecture, were pursued partly at a lazaretto on the island of Flores, and in part at the Hospital of San Sebastian at Rio Janeiro. Although the bodies of those who die of yellow fever are often either sterile, or entirely invaded by the various common forms of pathogenic bacteria, which can in no way be considered as the cause of the disease, in certain cases, Sanarelli has found present in relative purity, the organism which he considers the cause of the disease, and has named the bacillus, icteroïdes. The reason for the failure to find the bacillus in certain cases Sanarelli attributes to the fact that the cadavers are generally so completely in-

vaded by other microbes, which having gained entrance owing to the action of the bacillus icteroïdes, eventually injure or cause its total disappearance.

The bacillus icteroïdes must be sought for in the blood and the tissues, never in the gastro-intestinal canal, which is usually the seat of a luxuriant growth of the colon bacillus.

Sanarelli has found the isolation of the specific bacillus possible in 58 per cent. of the cases, and says that in some rare cases it may be effected during life. The reason for the difficulty of finding it is that the bacillus multiplies only to a small extent in the body before a quantity of toxin is produced sufficient to cause the grave picture of the complete disease. In the second place, the toxin, either by itself or in virtue of the profound lesions which it determines, especially in the digestive mucosa and the liver, facilitates in an exceptional way secondary infections of every kind. As the bacillus is found in the blood and the tissues, and never in the gastro-intestinal contents, the virus is manufactured, not in the intestinal canal, but in the blood and organs themselves.

The bacillus is small, with rounded ends, generally united in pairs in cultures, and in small groups in the tissues, and is pleomorphous. It is difficult to find in the tissues, except in cases where death has occurred without secondary septicemias, and even in these cases the number is so small that it is difficult to see in sections. Yet by the employment of suitable methods it may be found in the organs, usually united in little groups, always situated in the capillaries of the liver, kidneys, etc.

It develops well in all ordinary nutritive substances. In plate culture in ordinary gelatine it forms roundish colonies, transparent and granular. In time the colonies become opaque, but do not liquify gelatine.

The culture on agar-agar, presents a diagnostic means of the first importance. When the colonies develop in the incubator they assume an aspect which does not differ from that of many other microbial species—that is, they are roundish, gray, a little iridescent, transparent, with a smooth surface and regular margins. If instead of making them grow at a temperature of 37° C. they are left to grow at a temperature of 20° to 22° C., the colonies are like drops of milk, opaque, prominent, and with pearly reflections, completely different from those developed in the incubator. As this character, which for the present may be considered specific, can fortunately be obtained, even in twenty-four hours, it serves to establish, in the most rapid and certain manner, the bacteriological diagnosis of the bacillus icteroïdes.

The bacillus icteroïdes is a facultative anærobe, does not resist Gram's stain, slowly ferments lactose, more actively glucose and saccharose, but is not capable of coagulating milk; it strongly resists drying, dies in water at 60°, and is killed in seven hours by the solar rays, but lives for a long time in sea-water.

The specific microbe of yellow fever is pathogenic for the majority of domestic animals. In fact, whilst birds are completely refractory, all the mammals with which Sanarelli has experimented are more or less sensitive to the pathogenic action of the bacillus icteroïdes.

It kills white mice in five days, causing a general septicemia, with fatty degeneration of the liver.

In guinea-pigs it produces, in very small or large doses, a cyclical febrile disease, which always ends in death after eight to twelve days.

In dogs, injection of the bacilli into the veins produces a violent process which resembles in many characteristics human yellow fever, and at the necropsy the lesions are almost identical with those observed in man.

From the results of his researches regarding solely the morphology, biology, and the comparative pathology of the bacillus *icteroides*, Sanarelli draws the following conclusions:

(1) Yellow fever is an infective disease due to a well-defined micro-organism, capable of being cultivated in our ordinary artificial nutritive media.

(2) This micro-organism, which I have provisionally called bacillus *icteroides*, can be isolated not only from the cadaver, but also during the life of the patient suffering from yellow fever.

(3) Its isolation generally presents almost insurmountable difficulties, due partly to the constant intervention of secondary infections, and partly to the relative scarcity with which it is encountered in the organism.

(4) Such secondary infections, nearly always due to determinate microbic species, as the coli bacillus, the streptococcus, the staphylococcus, etc., may burst into the organism even a long time before the death of the patient, and thus death is sometimes due more to them than to the action of the bacillus *icteroides*.

(5) It is probable that one of the causes which give to the yellow fever of man its protean character is the nature and the manner of development of these secondary infections.

(6) The yellow fever infection, as much in man as in the lower animals, represents a disease with a cyclical course. During this period the specific microbe is found in the organs in very small numbers, and it is solely at the end of the cycle, about the seventh or eighth day, that it multiplies rapidly, and invades almost suddenly the whole organism, generally accompanied by other microbes, probably coming from the intestines.

(7) Only in cases which terminate in this manner—that is to say, which regularly complete the disease cycle—can the specific microbe, diffused in the blood and organs, be found with comparative facility. When an intercurrent septicæmia, or a precocious uræmic poisoning, puts an early end to this disease cycle, it is extremely difficult, if not altogether impossible, to isolate the bacillus *icteroides*.

The remainder of the lecture gives an extremely interesting account of the visceral lesions of yellow fever, of the causes of death, the chief of which are the specific infection, secondary infections, or uræmia, due to the acute parenchymatous nephritis, of the experimental effects of the toxin in man and animals, of the mode of infection, etc.

Suffice it to say that the toxin is found to produce the typical picture of the disease, as produced by the bacillus, both in man and animals, and that the mode of infection is uncertain. It is probably not by the alimentary canal, as shown by numerous records and experiments, and may possibly be by the respiratory tract, as the bacillus shows remarkable resistance to drying.

Points of great interest in the discussion for which we have not space, are the behavior of yellow fever on ships, and the evidence of the action of moulds in conserving and favoring the growth of the yellow fever bacilli. The limitations of space prevent more than a mere allusion to this part of the lecture, which will well repay perusal in the original, and which closes with the expression of a firm conviction that it will soon be possible to apply to man a preventive and curative treatment of yellow fever.

A QUALIFIED QUACK.

THE *Practitioner* publishes the following story, taken from a French newspaper. It certainly is an excellent illustration of the hold of quackery on the public:

In a fashionable quarter of Paris one "Alexis" does a roaring trade as a bone-setter and herbalist. To him one fine day there came a commissioner of police with an invitation to follow him to his office. The quack took the matter quite coolly, and, while preparing to obey the summons of the law, said to his servant, "Don't send any one away; I shall be back in a few minutes." The representative of the civil power hinted with a significant smile that his return might possibly be a little delayed. On arriving at the police office, "Alexis" asked the commissioner for a moment's private interview. This, after some demur, was granted. When they were alone, "Alexis" took from his pocket a diploma of Doctor of Medicine of the most authentic character, at the same time begging the astonished commissioner not to betray his secret, on the ground that he would lose all his practice if it were known that he was a regularly qualified doctor. He added, by way of explanation, that he had tried practice in the orthodox way and had nearly starved behind his brass plate. An inspiration came to him to start as a quack. He removed his plate, dropped his surname, gave himself out for a bone-setter—and he might have added, pointing to his rooms crowded with patients, "Si monumentum queris, circumspice!" This interesting story carries its truth on its face. I do not know whether "Alexis," doctor though he be, has much knowledge of medicine, but he evidently knows mankind.

Correspondence.

TWELFTH INTERNATIONAL MEDICAL CONGRESS.

NEW YORK, July 19, 1897.

MR. EDITOR:—In a letter dated July 7th, Dr. H. Kümmell, surgical director of the New General Hospital (*Neues Allgemeines Krankenhaus*) of Hamburg, in the names both of the local Hamburg and the general imperial committees of the Twelfth International Medical Congress, begs to invite American Congressists to inspect the hospital, and particularly the new hygienic establishments of the last few years. The medical men will be at the hospital daily, from 10 A. M. to 2 P. M. Still they request American Congressists to kindly notify them, if possible, of the days of their visits.

Very respectfully,

A. JACOBI, M.D.

THE WOODBRIDGE TREATMENT OF TYPHOID FEVER.

CLEVELAND, O., July 9, 1897.

MR. EDITOR:—If there is one thing which more than all else arouses the indignation of an honorable regular physician, it is to class him with, or compare him to, a "Cancer or kidney quack," and this has been done in the abstract of Dr. Upshur's criticism of the "Woodbridge treatment," in the report of the Medical Section of the American Medical Association, which appears in your issue of the 1st inst., in which these words occur: "The testimonials that had been filed regarding the efficacy of the treatment were of no more value than similar testimonials for some 'cancer cure' or 'kidney cure.'" The reports of honorable physicians, which are here compared to the "testimonial" given by the ignorant and deluded victims of the shameless quacksalvers, are the histories of cases of typhoid fever as seen at the bedside; and the circum-

stances under which they were rendered greatly enhance their value, and would, with a generous enemy, have shielded them from so infamous an attack. Reviewing these, it will be remembered that my announcement that typhoid fever can be aborted, was received with the bitterest dissent and a storm of the harshest kind of criticism; and for two or three years, the favorite amusement of "penny-a-liners" was to make sarcastic allusions to "the Woodbridge treatment." During this time a few physicians tried the treatment, were amazed at their results, and bravely published their reports, or sent them to me with kind words of encouragement. This emboldened me to ask for more reports, and I prepared a paper for the late meeting of my State Society here, which consisted almost entirely of brief quotations from these reports received up to that time, with clinical charts showing the most patient and painstaking observations—showing, too, that every procedure known to science had been called into requisition to verify the clinical diagnoses of the cases reported, and showing 5,449 cases of typhoid fever treated, with 105 deaths.

Since that paper was read on May 21st inst., I have received more than 200 additional reports, covering 2,408 cases treated, with 45 deaths; so that the record now stands 7,857 cases treated, with 150 deaths—or a death-rate of 1.90 per cent. and an average duration of illness in the 4,935 cases in which this is given, of 12.7 days. Hundreds of these observers are physicians of the highest social and professional standing, whose integrity has never been questioned, and it is their reports of cases and candid expressions of opinion which Dr. Upshur stigmatizes, as "testimonials of no more value than those given to some cancer cure or kidney cure"; and he does this after confessing that he has no practical knowledge on the subject, and showing by his allusions that he has very little theoretical acquaintance with it. Time, and the discriminating judgment of the medical profession enlightened by experience, will render a just verdict on the abortive treatment of typhoid fever.

I am, sir, most respectfully yours,

JOHN ELIOT WOODBRIDGE, M.D.

A CAUTION AGAINST THE USE OF ANTEFEBRIN ON EXTENSIVELY BLISTERED SURFACES.

BOSTON, July 13, 1897.

MR. EDITOR:—The present writer has just had to help care for a severe case of acetanilid poisoning in a young man of nineteen years, in which the drug was absorbed from an immense burn of the second degree involving the entire back, at least two square feet being affected.

On the sixth day after the accident, the discharge being rather profuse and offensive, the drug (acetanilid) had been used to hasten cicatrization and to render the wound less offensive.

From disuse of the old endermic method of administering medicine, we are apt to forget how much a recently blistered surface can absorb.

Four hours after the application this patient was in collapse, and with livid lips, black finger-nails and general cyanosis, he looked startlingly like a recently-drowned corpse. At times the pulse could not be felt at the wrist, and he could not be aroused except by the most powerful stimuli, and even these failed at the climax of his depression. When aroused, his mind was clear and no pain was complained of.

The treatment was cardiac and general stimulants, hypodermically and by the mouth, the application of heat and inhalation of oxygen gas. The acetanilid was wiped off with oil and vaseline from the burnt surface and zinc ointment and caron oil (one to four) applied. It was several hours before he could be pronounced out of danger.

Yours truly,

E. S. BOLAND, M.D.

METEOROLOGICAL RECORD

For the week ending July 10th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 4,475; under five years of age 2,094; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping cough, erysipelas, and fever) 1,195, diarrheal diseases 886, consumption 335, acute lung diseases 245, diphtheria and croup 127, typhoid fever 36, scarlet fever 33, measles 28, whooping-cough 27, cerebro-spinal meningitis 24, erysipelas 11, small-pox 1.

From scarlet fever Philadelphia 13, New York 7, Brooklyn 4, Chicago and Boston 2 each, Baltimore, Cincinnati, Worcester, Lowell and New Bedford 1 each. From measles Chicago 8, Cleveland 6, Brooklyn 3, New York, Philadelphia, Pittsburg and Springfield 2 each, Baltimore, Lowell and Fitchburg 1 each. From whooping-cough New York 7, Brooklyn 6, Chicago 4, Boston, Cincinnati and Springfield 2 each, St. Louis, Cleveland,

Washington and Haverhill 1 each. From cerebro-spinal meningitis New York 7, Boston 6, Worcester 4, Somerville 2, Baltimore, Chelsea, Newton, Waltham and Woburn 1 each. From erysipelas Chicago 5, New York and Boston 3 each. From small-pox New York 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,992,524, for the week ending July 31, the death-rate was 14.7. Deaths reported 3,106; acute diseases of the respiratory organs (London) 127, measles 156, diarrhea 82, whooping-cough 77, diphtheria 41, scarlet fever 34, fever 19.

The death-rates ranged from 10.3 in Croydon to 25.4 in Preston; Birmingham 17.3, Bradford 12.4, Cardiff 13.8, Gateshead 15.0, Hull 13.2, Leeds 11.5, Leicester 14.3, Liverpool 21.1, London 13.5, Manchester 19.0, Nottingham 12.1, Sheffield 14.8, Swansea 12.0.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 10, 1897, TO JULY 16, 1897.

CAPTAIN CHAMPE C. McCULLOCH, JR., assistant surgeon, is relieved from duty at the Army and Navy General Hospital, Hot Springs, Ark., to take effect upon expiration of his present leave of absence and ordered to Fort Barrancas, Fla., for duty, relieving CAPTAIN WILLIAM C. GORGAS, assistant surgeon.

CAPTAIN GORGAS, upon being thus relieved, ordered to take station at New York City, and assume duties of attending surgeon and examiner of recruits, relieving CAPTAIN CHARLES RICHARD, assistant surgeon.

CAPTAIN RICHARD, on being thus relieved, is ordered to Fort Monroe, Va., for duty.

MAJOR WILLIAM H. CORBUSIER, surgeon, upon the arrival at Fort Monroe, Va., of CAPTAIN RICHARD, will be relieved from duty at that post and is ordered to Angel Island, Cal., relieving MAJOR BENJAMIN F. POPE, surgeon.

MAJOR POPE, upon being thus relieved, is ordered to Columbus Barracks, O., for duty, relieving CAPTAIN JAMES E. PILCHER, assistant surgeon.

CAPTAIN PILCHER, on being thus relieved, is ordered to Fort Crook, Neb., for duty.

CAPTAIN CHARLES F. KIEFFER, assistant surgeon, upon the arrival of CAPTAIN PILCHER at Fort Crook, Neb., is ordered to Fort Meade, S. D., for duty at that post.

FIRST-LIEUT. HENRY R. STILES, assistant surgeon, upon the arrival of CAPTAIN KIEFFER at Fort Meade, S. D., is ordered to Columbus Barracks, O., for duty at that post.

CAPTAIN BENJAMIN L. TEN EYCK, assistant surgeon, upon the arrival of FIRST-LIEUT. STILES at Columbus Barracks, O., is ordered to Army and Navy General Hospital, Hot Springs, Ark., for duty.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE TWO WEEKS ENDING JULY 20, 1897.

SAWTELLE, H. W., surgeon. To inspect quarantine stations on coasts of Louisiana, Mississippi, Alabama and Florida as far as and including Pensacola. June 29, 1897.

WASDIN, EUGENE, passed assistant surgeon. To proceed to Mobile, Ala., for temporary duty. July 3, 1897.

MAGRUDER, G. M., passed assistant surgeon. To inspect quarantine stations on the coast of Texas. June 29, 1897.

GREENE, JOS. B., assistant surgeon. On rejoining station at Detroit, Mich., to proceed to Cape Charles Quarantine for duty. June 28, 1897.

GRUBBS, S. B., assistant surgeon. To remain at Detroit, Mich., until further orders. June 28, 1897.

RUSSELL, HOWARD C., assistant surgeon. To proceed to New York, N. Y., for duty. July 1, 1897.

MCKRAY, R. D., surgeon. Granted leave of absence for thirty days. July 10, 1897.

GASSAWAY, J. M., surgeon. Upon being relieved by Passed Assistant Surgeon P. C. KALLOCH, to proceed to San Francisco, Cal., and assume command of Service. July 9, 1897.

STONER, GEORGE W., surgeon. To inspect quarantine station for the port of New York, N. Y. July 10, 1897.

GODFREY, JOHN, surgeon. Upon being relieved by Surgeon J. M. GASSAWAY, to proceed to Detroit, Mich., and assume command of Service. July 9, 1897.

KALLOCH, P. C., passed assistant surgeon. To proceed to Cairo, Ill., and assume command of Service. July 9, 1897.

CARRINGTON, P. M., passed assistant surgeon. To inspect quarantine stations on coasts of Georgia, South Carolina, North Carolina and Virginia, beginning at St. Mary's, Ga., and continuing to and including West Point, Va. July 7, 1897.

PERRY, T. B., passed assistant surgeon. To proceed to Evansville, Ind., and assume temporary command of Service. July 6, 1897.

YOUNG, G. B., passed assistant surgeon. Granted thirty days' leave of absence from August 5, 1897. July 9, 1897.

SERAGUE, E. K., passed assistant surgeon. Granted five days' leave of absence. July 6, 1897.

DECKER, C. E., assistant surgeon. Granted twenty-six days' leave of absence. July 7, 1897.

PROCHAZKA, EMIL, assistant surgeon. Granted ten days' leave of absence. July 1, 1897. Placed on waiting orders from and including July 11, 1897. July 10, 1897.

SOME CASES OF CYSTITIS IN WOMEN.¹

BY EDGAR GARCEAU, M.D.,

Surgeon to Out-patients, Free Hospital for Women, Boston; Clinical Instructor in Gynecology in Tufts Medical School.

CASE I. Cystitis of a year's duration caused by tuberculosis of the right kidney. Nephrectomy. Recovery.

Miss S. was a girl twenty-one years old. Her father died of cancer of the stomach, and there was a tubercular history in the family. She was delicate-looking and had a fair complexion. Since childhood she always had had some pain in the right lumbar region; and she says she could never run and jump as other children do, because exertion always brought a pain. When she was older, even going upstairs was painful. She was able to attend to her work (light housework), however; for the pain was by no means a prominent feature in her case. The symptoms on the part of the bladder began only a year before the operation was performed, which is remarkable in view of the probable long duration of the renal affection. Frequency of micturition was the first symptom, and later painful micturition during the act. The desire to urinate was irresistible, and there was also some *teuesmus*. Just before the nephrectomy she was urinating every fifteen minutes or so by day, and she had to get up four or five times each night. From the absence of purulent affections of the genital organs, and, in addition, from the fact that the meatus was well closed, Skene's labia being normal, and from the fact that the obstinate cystitis was of long duration and was present in a young girl with tubercular diathesis with a history of lumbar pain, it was thought that the cystitis depended upon tuberculosis of the kidney. Cystoscopic examination disclosed an inflamed bladder with ulcerations around the right ureteral orifice and also scattered throughout the rest of the bladder; the right ureteral eminence had disappeared, and its place was occupied by an ulcer with a yellowish base, presenting the appearance of gradual necrosis. The renal catheters were inserted in each ureter and the urine drawn presented the following characteristics:

RIGHT KIDNEY.—Urea, 1.5 per cent. Much sediment, chiefly pus; contains also hyaline casts, renal cells, some blood and *tubercle bacilli*.

LEFT KIDNEY.—Urea, 3.5 per cent. Slight sediment, chiefly blood (trauma); nothing else.

Nephrectomy was performed June 20, 1896. Before operation palpation of the kidney was negative, there being no enlargement.

The kidney was removed by lumbar incision, without special difficulty on account of the thinness of the patient and the absence of adhesions. Unfortunately, the clamp on the renal end of the ureter was loosened accidentally, and the pus coming out infected the wound. This necessitated drainage and led to the formation of a fistula. At the end of the operation respiration became embarrassed and ceased altogether. Artificial respiration was done with good effect, and stimulants given. This difficulty was met with in another case, and is due no doubt to the constrained position on the side, which interfered with the action of the respiratory muscles. The convalescence

was uneventful, except that the bladder was still very irritable. As she was of a very nervous temperament, and as even the mildest irrigations were painful, it was thought best, when she was strong enough, to cauterize the ulcers with solid nitrate of silver. This was accordingly done under ether on July 10th, twenty days after the operation. Practically the whole bladder was cauterized. The result was gratifying. At once she urinated only four times a day and three times at night, and was perfectly comfortable. This relief has lasted eight months, or until the present time. The treatment during this period has been irrigations and vesical sedatives.

At the present writing the patient is urinating four times a day and two or three times a night. She has no pain whatever, is perfectly comfortable, and considers herself well. She has gained in flesh. The fistula in the loin, after discharging, from time to time, a silk ligature, has now become almost closed, and secretes only a drop of pus each day; an early, complete closure is looked for. A cystoscopic examination practised in May, showed a healthy bladder membrane, of normal pale-gray hue, with the exception of two or three suspicious-looking points having the appearance of tubercles. These were cauterized with solid nitrate of silver fused on the end of a probe. Inasmuch as the process can be watched and treated locally, and is of small extent, and from the fact that healing has been going on uninterruptedly for eight months, a complete recovery is hoped for.

It is of interest to note that, before nephrectomy, 900 c. cm. of urine was the daily average secreted, while, after nephrectomy, it at once rose to 1,200 c. cm., and remained at that point during the forty days during which it was measured.

The kidney removed was examined by Dr. Wm. H. Prescott, who found an abscess, the size of an English walnut, situated in the cortex of the kidney, which communicated with the pelvis; tubercles were found scattered here and there in some of the remaining portions of the kidney.

The point of interest in this case is that the treatment had been directed solely to the bladder, the kidney having been entirely overlooked. As has already been mentioned, pain in the lumbar region was not severe, and never had been, and the long history of pain was elicited only in the course of careful questioning. It is of great importance to note that an abscess of the kidney may exist without exciting marked symptoms which are strictly renal (see also Case IV). Early ureteral catheterization in these cases is therefore indicated. It is not supposed that the nephrectomy would have been very beneficial if the bladder had not been thoroughly cauterized. Such a sudden stimulus to cicatrization carried with it danger of subsequent over-contraction, and this was realized when it was done. Such a sequel did not, however, occur, for at the last cystoscopic examination in the knee-chest position, which allows the bladder to become distended, the viscus was noted to be of normal size. So far as the author knows, this method of treatment, carried to such an extent, is original, and would seem applicable to similar cases.

With reference to immunity from tuberculosis after nephrectomy for tuberculous kidney, the statistics of Palet² are interesting. He reports two cases of Bar-

¹ Read before the Gynecological Section of the Massachusetts Medical Society, February 24, 1897.

² Examined by Dr. W. H. Prescott.

³ Palet: Des Resultats Immédiats et Éloignés de la Néphrectomie dans la Tuberculose Rénale, Thèse de Lyon, 1893.

denheuer and Martin,⁴ in which there had been no recurrence for eight years. These were the best results. Other cases collected were as follows: In 16 cases, no recurrence after six months; in 12, none after one year; in six, none after two years; in six, none after three years; in seven, none after four years; in one, none after five years; in three, none after six years. The general, immediate mortality of nephrectomy was, in 136 cases of renal tuberculosis, 37.5 per cent.

CASE II. Cystitis of seven months' duration. Double ureteritis or pyelitis, hyperemia of the kidneys, retroversion, purulent endocervicitis.

This patient was twenty-one years old and unmarried. For a year she had had severe backache and a leucorrheal discharge. But her principal trouble was referable to the bladder. She had to urinate every half-hour during the day and five or six times at night. Under these circumstances she lost her health, became thin, anemic and miserable. On examination, the uterus was found retroverted, and it was remarked that a purulent discharge bathed the meatus of the urethra. This proceeded from the uterine cavity. The meatus was not patulous. A cystoscope was introduced into the bladder and a severe grade of cystitis was seen. Injection of the blood vessels was universal; here and there small superficial ulcerations were observed with yellow bases; patches of inflamed lymphoid nodules redder than the rest of the bladder wall were thickly scattered about. The whole appearance corresponded to the class of cases described by Alexander,⁵ and to which he has given the name, nodular cystitis. The ureteral eminences were both injected, and were very prominent. The renal catheters were introduced into the ureters, and the urine drawn presented the following characteristics:

RIGHT KIDNEY⁶—Urea 2.02 per cent. Slight sediment; small amount of pus and blood, uric-acid crystals; a few hyaline and fine granular casts, some very large; no tubercle bacilli.

LEFT KIDNEY.—Urea 1.26 per cent. Considerable sediment; much pus and blood, normal and abnormal; many uric-acid crystals, more than the right; occasional hyaline cast; a few round cells; no tubercle bacilli.

Amount of urine in twenty-four hours, 1,000 c. cm.

The treatment was correction of the retroversion, and insertion of a pessary; and local treatment of the bladder combined with vesical sedatives to dilute the urine and make it bland. In five weeks, under permanganate-of-potash irrigations, the cystitis was cured so that she urinated only three times a day and not at all at night. The leucorrheal discharge was held in check by zinc-sulphate douches, and the pessary relieved the symptoms of retroversion completely. A cystoscopic examination was now made to discover why a slight amount of pus still persisted in the urine. The bladder mucous membrane was absolutely normal in appearance. It is feared, therefore, that the pus proceeds from the upper urinary passages, and that reinfection may happen. It is possible, however, that this may not occur if the bladder membrane remains intact for, as Bortolanelli⁷ has pointed out, cystitis is never produced by micro-organisms unless there is some pre-existing pathological condition of the mucous membrane of the bladder. This result is confirmed by other observers, notably Biell and Kraus⁸ who injected

bacteria into the veins of animals, and who invariably found them in the urine, the bacteria not having given rise to cystitis in their passage through the bladder. A further proof of the innocuousness of bacteria in healthy bladder membrane is furnished by observations of medical students who are engaged in dissecting. Bacteriuria is not uncommon under these circumstances. The urine is frequently very foul and contains myriads of bacteria.

The etiology in this case is probably that of ascending infection through the meatus and urethra. It is probable that the infection extended up into both ureters and into the pelves of the kidneys. It is impossible to say definitely whether ureteritis or pyelitis is now present since the examination of the sediment is not conclusive. That both were present at the time before treatment was instituted is fairly certain—ureteritis, from the fact that the ureteral eminences were very prominent and deeply injected at the first cystoscopic examination; pyelitis, from the presence of casts, though these have since disappeared. Of the two, pyelitis is the more probable on account of the absence of severe symptoms which usually accompany ureteritis. This leads us to suspect that there may be, after all, a descending infection as well as an ascending one. Finally, there are those cases in which infection, at first ascending, may establish a chronic ureteritis or pyelitis, which, in turn, when the bladder has been cured, may act as a source of re-infection in a descending direction, and thus a vicious circle is established, which may explain the extreme obstinacy of some cases of cystitis (see Cases III and VI). That a cure of the bladder was possible with suppuration in the upper tract is quite remarkable.

It is thought that a recurrence is not unlikely in the present case.

CASE III. Gonorrheal cystitis of twenty years' duration. Double ureteritis. Prolonged local treatment. Cystotomy.

Miss F., forty years old, was a woman of slight build who contracted gonorrhea when she was twenty years old. Ever since that time she has suffered intolerably from cystitis. Her sufferings at times were so severe as to make her almost "frantic," and treatment has been during this time very unsatisfactory. Irrigations and medicines would relieve for a while, but were never permanent in their effect. The case was first seen by the author in June, 1896. At that time the patient was urinating twelve times a day and six times at night. Urination was not painful, and the suffering proceeded entirely from a constant irresistible desire to urinate, which may be expressed by the word "nagging." She was never free from it night or day. For the past few years sleep was procured only by taking drugs; she was, however, fortunate in having escaped the morphine habit.

The cystoscope showed the neck of the bladder and urethra moderately hyperemic, but here and there on the bladder wall were small red spots indicative of nodular cystitis. The blood-vessels throughout the bladder were injected. A long course of local treatment was now instituted, extending from June to November, 1896. At the end of this time, there being no improvement whatever, or at least only temporary improvement, the operation of cystotomy was proposed and accepted. This was accordingly done on November 2d; but, contrary to expectation, no immediate relief followed this treatment. The patient seemed to

⁸ Bacteriuria; Hermann Goldenburg, New York Medical Record, August 15, 1896.

be much worse. This was thought to be due to severe spasm of the sphincter vaginae, which retained the urine and interfered with drainage. But when this was allayed by sedatives and no relief followed, even some weeks after the operation, it was thought that the failure to get relief was due to a suspected ureteritis which was supposed to be on the left side. In July, a careful examination had been made with the result that a tender left ureter was felt *per vaginam* slightly larger than the right one. In addition to this, Reynold's⁹ symptom of ureteritis — pain on deep pressure at a point one inch above the middle of Poupert's ligament — was present. The ureteral eminences on both sides had always been prominent, but there had never been any eversion of the mucous membrane of the ureter. In order to make certain of the diagnosis both ureters were catheterized, and urine drawn from each one. The characteristics were as follows:

RIGHT KIDNEY. — Urea 1.13 per cent. Slight sediment, chiefly pus; some blood, many dense caudate cells; many medium-sized pavement cells; a few granular round cells of small size. No casts.

LEFT KIDNEY. — Urea .88 per cent. Much sediment, chiefly pus; some blood, many medium-sized pavement cells free and in sheets; some small round cells. No casts.

Incidentally it may be said that casts were never found at any examination of the urine. The diagnosis of double ureteritis, chiefly on the left side, was thus made evident, and the failure to secure immediate relief explained.

At present the patient is much more comfortable; the inflammation of the bladder is subsiding; she sleeps without the use of drugs, and is gaining flesh.

In this case it was regretted that early catheterization of the ureters was not done; much time might have been saved had a correct estimate of the lesions been made. Without a doubt the purulent ureteritis acted as a constant source of re-infection of the bladder. An early cystotomy should have been performed. The long duration of the disease should have been an indication of the involvement of the upper urinary passages.

CASE IV. Cystitis of four years' duration, preceded by attacks of renal (?) colic. Catheterization of ureters; nephrectomy; suppurative pyelo-nephritis, with multiple abscesses in the cortex; dilated ureter. Recovery.

Miss T. was a young girl, twenty-two years old, of medium height and good bony development. She was, however, much reduced in flesh by her long suppurative disease. Her early history was not remarkable, except that she always had suffered from severe sick-headaches. This suggested uric-acid diathesis, and further evidence of this dyscrasia was furnished by the history of three severe attacks of "cholera morbus" (renal colic?), as she expressed it. Two of these attacks happened between the ages of twelve and eighteen, before the bladder symptoms began; and the third attack happened in July, 1895, about three years after the beginning of the cystitis. Once only did she attribute the attack to error in diet; the other two came on in the night with great suddenness and prostrated her. The pain in all of them was referred to the pit of the stomach. There was no family history of rheumatism, and the patient had never suffered from this disease. She had not been nervous.

There had never at any time been any localized pain in either lumbar region; but there had been quite persistent backache, which was not localized but general, and had been looked upon as a symptom of general debility from long illness, and had not presented any characteristics worthy of special comment. Her general health had been much reduced, but there was no cough or other symptoms denoting any tubercular disease in any part of the body.

The trouble with the bladder began gradually in June, 1893. At first there was only frequent micturition, not attended with pain; in September the frequency had increased, and there was pain during the act. She had no rest night or day from the constant irresistible desire to urinate, and she soon became reduced to a state of chronic invalidism. The stomach retained its functions well until July, 1896. At that time there was an attack of gastritis, during which she could retain nothing but peptonized milk; it lasted five weeks and gradually disappeared.

The author saw the patient for the first time in January, 1897. The long duration of the case, the quantity of pus in the urine, the tubercular history in the family, and the powerlessness of local treatment to cure the disease, suggested at once tuberculosis of the kidney in the abscess stage. On the other hand, the probable uric-acid diathesis, with the history of probable renal colic indicated a possible calculous origin. Ureteral catheterization was proposed and accepted. Under either the bladder was found to be in a state of intense inflammation. The left hemisphere was less inflamed than the right; in the right portion of the bladder there were numerous small superficial ulcerations with yellow bases. The left ureteral orifice was found after some search and a catheter put in up to the kidney; on the right side the landmarks were entirely gone, the ureteral eminences having been eroded by gradual ulceration. The orifice was finally located by seeing pus well up from a small pit-shaped depression near the centre of the trigonum in an anomalous position. A catheter was likewise introduced up to the kidney on this side. The ulcerations were now touched with fused silver nitrate.

The urine drawn presented the following characteristics:

RIGHT KIDNEY.¹⁰ — Urea .63 per cent. Pale color; large sediment, consists chiefly of pus; some round epithelium of small size; occasional hyaline cast; too much pus to determine the number of casts; a few doubtful calcic oxalate crystals; no *tubercle bacilli* and no *bacteria* of any kind.

LEFT KIDNEY. — Urea 2.40 per cent. Red color; slight sediment, consists chiefly of blood (traumatic); a few calcic oxalate crystals. No casts, no pus, no *tubercle bacilli* nor *bacteria*.

Dr. Prescott's diagnosis was pyelo-nephritis of the right kidney, of probable calculous origin; this in view of the absence of tubercle bacilli and the presence of the few crystals. It must be confessed that the author did not agree with this diagnosis, and was more inclined to favor the view that tubercle bacilli were present but not found — which sometimes occurs; the presence of calcic oxalate in the urine of debilitated persons is so frequently the rule and not the exception that these few crystals were regarded as a complication and of no special significance.

The kidneys were palpated under ether at the time of the cystoscopic examination, but *no abnormality could be detected in either of them*, and there was no apparent enlargement. At the operation, however,

⁹ Edward Reynolds: Some Aspects of Ureteritis in Women. Transactions of the American Gynecological Society, May, 1896.

¹⁰ Examined by Dr. W. H. Prescott.

the kidney was found to be about twice the normal size; but as it was adherent to the descending portion of the duodenum, it was held abnormally high and immovably fixed, so that it could not have been palpated externally. On vaginal examination the right ureter was thought to be a little larger than the left one. In view of the great amount of pus proceeding from the right kidney, and the small amount of work being done by it, as measured by the excretion of urea, it was deemed advisable to make an exploratory incision and if necessary do a nephrectomy. This was accordingly done on February 5th. A lumbar incision, extra-peritoneal, was made and the kidney was exposed. A soft spot presented which was aspirated and a small amount of pus obtained. No stone was felt. On incising the pocket it was felt to be single, and did not communicate with any other, nor apparently with the renal pelvis; but in view of the large size of the kidney and the long duration of the case, and the small amount of urea, it was thought that the kidney was thoroughly disorganized. Such proved to be the case.

The nephrectomy was laborious and difficult on account of dense adhesions to the duodenum, and on account of the friability of cortical substance; the kidney was finally enucleated from its capsule and the renal vessels, small, tied off. The kidney was riddled with abscesses; there was no stone. The ureter was dilated to a very large size (as large as the forefinger), and its lumen admitted the little finger. This suggested stone in the ureter; but as the patient at this point stopped breathing, there was no time for investigating this point, so it was reluctantly left for a possible future operation. Artificial respiration was done and stimulants given; she rallied and the wound was closed, and she was put in bed.

The convalescence was uneventful. The daily amount of urine secreted after operation averaged 960 c. cm. in twenty-four hours. When last heard from, in May, the patient was free from pain, and was urinating once in three hours. She cannot hold her water longer than this and it is doubtful if she will be ever able to do so owing to the contracted condition of her bladder.

The pathological report¹¹ showed simple suppurative pyelo-nephritis with numerous abscesses in the cortex; the kidney was honeycombed with abscesses from the size of a bean to that of a walnut; careful examination failed to show the presence of tubercle anywhere. Cultures made from the pus aspirated were sterile. The process was therefore an old infective one at a stage when bacteria were no longer present.

In this case there were several points worthy of comment. In the first place it shows how far a pyelo-nephritis may progress *without giving any symptoms strictly referable to the kidney*. The absence of renal symptoms is probably due to the distensible nature of parenchyma of the kidney, as well as to the fact that drainage through the pelvis and ureter is almost constant. For these reasons pressure on nerves must be very slight; hence the absence of pain. The renal catheter was of the greatest aid in making the diagnosis. All the symptoms being vesical, it is easy to see how treatment should have been directed exclusively to that organ while the kidney, being the silent focus of the trouble, was overlooked. The adhesions of the kidney to the duodenum, which kept it abnormally high under the ribs, prevented the examiner from ap-

preciating its large size, and still further in this way masked the diagnosis. At the operation when a single pus sac was opened it was a question whether there were others or not; the long duration of the case, the size of the kidney, and the low amount of urea, made it probable that there were. Still it was a debatable point whether to do nephrectomy or simply drain, as has been advised. The dilated state of the ureter calls for special mention. It is probable, in the absence of tubercle bacilli, that the disease was in the first instance calculous, and that a stone had lodged in the ureter at some point, causing dilatation above it. Fenger¹² reports a case in which four stones were extracted, by lumbar incision, from the ureter at a point two inches below the renal pelvis; they had been arrested by a valve-like fold in the ureter. The patient recovered. Finally, the abnormal position of the ureteral orifice in the bladder, and the obliteration of the eminence by ulceration, as well as finding the orifice by seeing pus well up, are facts to be borne in mind in dealing with a similar case.

(To be continued.)

ANOMALIES OF MUSCULAR BALANCE.¹

BY OLIVER F. WADSWORTH, M.D., BOSTON.

IN the short time allotted to me I can hope to give but a brief and imperfect sketch of my subject. And it must be admitted that the problems involved in the action of the ocular muscles and our attempts to remedy their deficiencies are by no means fully solved. Still, knowledge in this direction is gradually increasing.

The class of anomalies of which I am to speak does not include such faults of balance of the ocular muscles as cause an evident deviation of one eye, as in strabismus. Whether the want of balance be due to a preponderance of strength of one set of muscles over their antagonists, to a faulty position of the attachments of the muscles to the globe, or some other cause, the essential element in these cases is that the proper direction of the two eyes with regard to each other is habitually maintained, although at the expense of abnormal or excessive exertion on the part of one or more muscles.

The existence of such cases has long been recognized; the terms insufficiency of interni or externi to define them and of muscular asthenopia to denote the fatigue occasioned were long employed. As these terms imply, it was mainly to want of balance between the internal and external recti that attention was directed, and the condition was studied chiefly as it affected the efficiency of the eyes for near work. In the last ten years, however, a widespread interest in the subject has been aroused in this country, and it has become manifest that not merely are these defects of balance more frequent, but the functional disturbances to which they may give rise are more numerous and of greater variety than was formerly recognized, while their effects may be seriously felt in distant as well as in near vision.

As men are constituted, it was only to be expected that extravagant assertions should be made as to the importance and deleterious influence of these anomalies.

¹ Read before the Massachusetts Medical Society, June 8, 1897, and recommended for publication by the Society.

¹¹ By C. G. Cumston.

¹² Fenger: American Journal Medical Sciences, December, 1896.

Indeed, it seems to have been the publication of such assertions that first stimulated the recently awakened investigations. We are all of us cognizant of isolated cases in which a comparatively slight cause has produced grave functional disorders, but that is far from establishing a general law. A case of spastic torticollis which had persisted for years and was rapidly cured by the division of one of the superior recti muscles, I reported in the "Transactions of the American Ophthalmological Society," in 1889, but it does not follow that many cases of torticollis are of similar origin. The claim that a large proportion of cases of epilepsy and chorea owe their inception to faults of ocular balance, or to errors of refraction, or to both combined, and may be cured by the correction of these causes, has been sufficiently disproved.

The usual symptoms caused by imperfect balance of the ocular muscles are fatigue of the eyes, headache, which may be located at any part, but in my experience is most commonly referred to the back and base of the skull, vertigo and nausea. Even vomiting occurs in some cases, not depending on severity of the headache. Occasionally there are vicarious sensations. One of my patients complained of a coppery taste on the use of the eyes, which sometimes lasted throughout the following day. Dizziness in some cases is excited by moving objects and brought on by driving, or riding in the cars, or walking in a crowded street. In most instances the symptoms are not different from those with which we are familiar as caused by errors of refraction, and it may be said in passing that errors of refraction are much the more common source of such symptoms.

The defect of balance may be such as to incline the eyes to converge or to diverge, or to incline one eye to be directed higher than the other. And the latter defect may occur in combination with either of the others. The terms proposed by Dr. Stevens to denote these conditions have proved very useful. Thus esophoria denotes a tendency to convergence, exophoria to divergence, and hyperphoria a tendency of one eye to point higher. We say right or left hyperphoria according as the right or left eye tends upward. The amount of the defect is measured by the strength of the prism required to correct it.

There is general agreement that the conditions in which one eye tends to point higher, hyperphoria, is much more disturbing than esophoria or exophoria. And the reason for this is not far to seek. The natural ability of an eye to turn upward or downward with reference to the other in order to maintain binocular single vision is much less than its ability to turn relatively inward or outward for the same purpose. Fortunately, hyperphoria is much less common. Whether disability more frequently occurs from esophoria or exophoria there is not the same unanimity of opinion. My own experience leads me to the belief that exophoria is the more usual cause of trouble. Esophoria is indeed the more common, but a given degree of esophoria is of less consequence than the same degree of exophoria. On the other hand, it is not very uncommon to find an esophoria of so large an amount that, if the defect of balance were in the opposite direction there would almost inevitably be frank divergence, and hence no exophoria. For, as has been said, that a case should be classed among these affections both eyes must, in spite of the lack of muscular equilibrium, maintain the proper direction.

The position of balance in the primary position of the eyes, that is, when the head is erect and the eyes are directed straight forward toward the horizon, is usually different, so far as the lateral muscles are concerned, from that which exists when the eyes are directed somewhat downward and to a nearer point, as in ordinary work or reading. Formerly, in considering the question of balance the condition found at the reading distance was generally regarded as of main importance. Now, while the state of the balance at the reading distance is not to be neglected, chief emphasis is placed on the condition when the eyes are directed horizontally and to a distant object. Both theory and practice indicate that the latter view is the more accurate.

The methods now employed for the detection of faulty equilibrium are modifications and improvements of tests long in use. To describe them would make too great a demand on the limited time at my disposal and lead me into technicalities which I wish to avoid. It should be said, however, that in every case careful correction of errors of refraction should precede the examination of the muscular balance, and such examination should be made only while the glasses which correct any errors of refraction are worn. Only under this condition can the tests be considered reliable.

The means of treatment are mainly two—the wearing of prisms and tenotomy of the preponderating muscle. The first is but palliative and suffices to correct the defect only when it is of moderate degree, since prisms stronger than 4° or 5° cannot be worn with comfort on account of the color dispersion they produce, and for other reasons. If the amount of the defect is comparatively small, prisms may be sufficiently effective. And if, because of accompanying errors of refraction, glasses are to be constantly worn in any event, the addition of prisms may answer every demand. With higher degrees prisms can only partially correct; yet partial correction may give comfort.

The radical treatment, tenotomy, when successfully employed, offers decided advantages. By tenotomy alone can the greater defects be even approximately corrected, and although with lesser defects prisms may be efficient it is only on the condition that they be worn constantly, and this is often a not inconsiderable inconvenience. Yet the performance of tenotomy is not to be lightly undertaken. In the conditions with which we have here to do its amount must be determined with the utmost care, and not even the operation for cataract demands more skill and judgment on the part of the operator. Above all, the desired effect is not to be exceeded. An individual who all his life has been training a set of muscles to act in an abnormal way to overcome the defect, will, if he is suddenly called on to make those muscles act abnormally in the opposite direction, although in less degree, probably be in a worse state than he was before. It is decidedly better therefore to stop short of the total effect desired rather than to run the risk of exceeding it. And an operation that only approximately corrects is often all that is necessary. But if too much effect is unintentionally produced, the excess should always be immediately corrected, or even somewhat over-corrected, by bringing the severed tendon forward with stitches. To fulfil these requirements intelligently every tenotomy should be done under the anesthesia of cocaine, never under ether.

The exact amount of the defect it is not always

easy to determine. The application of the tests for its discovery requires judgment and experience and should be repeatedly made before a definite opinion is formed. As, in the state of refraction known as hypermetropia, the ciliary muscle, constantly called on to act to excess whenever any effort of vision is made, is often unable to fully relax when a glass neutralizing the hypermetropia is placed before it, so here, the muscle trained to excessive action often does not abandon such action readily and the true balance does not become apparent. It is therefore almost invariably better, even if tenotomy seems advisable, to precede it by the use of prisms for a few weeks. In this way we may learn something of the effect of at least a partial correction of the symptoms, and we not infrequently find that the defect is greater than at first appeared. It is, I believe, in great part owing to this inability of the muscle to readily give up its habit of excessive action that, in some cases, a few days or weeks after a tenotomy its immediate effect is found to have apparently diminished. Rarely the reverse occurs, the result of an operation which is at first satisfactory proving after a few days to be somewhat too great. Sometimes this excess disappears again after a time spontaneously. If it does not the tendon must be brought forward.

The number of persons in whom some want of equilibrium of the ocular muscles exists is very great. In the vast majority of them, however, the amount of the defect is small, and when it concerns only the lateral muscles, as is usually the case, is seldom of any importance. Moderate defects of balance in the muscles that raise and depress the eyes, and higher degrees in the lateral muscles, may and often do cause serious functional disturbances and require correction either by prisms or tenotomy.

It need hardly be added that in many cases the condition of the eyes is only one factor in the causation of the symptoms, even when these are the more common ones of ocular fatigue and headache, but it is none the less a factor to be reckoned with, and the correction of it alone many times will bring relief.

SOME PHASES OF LACHRYMAL OBSTRUCTION, AND THEIR TREATMENT.¹

BY DAVID HARROWER, M.D., WORCESTER.

AMONG the most annoying and persistent troubles that we have to treat in connection with the eye, we find those of the tear passage not the least. The lachrymal secretions come from the lachrymal gland and from the conjunctiva and pass through the superior and inferior puncta into the passages that lead into the sac, and from that into the lachrymal duct and empty into the nasal fossa below the inferior turbinated bone. At the spot where the lachrymal sac passes into the nasal or lachrymal duct, is the point where we are liable to have most of the pathological obstructions that occur. In its course the lachrymal duct passes backward and outward from the vertical, the entrances to the ducts being nearer together than the exits.

The cases of lachrymal obstruction that present themselves for treatment are the acute and chronic. In the chronic case, the patient comes complaining of

epiphora, or tears running over the lids, and generally of a swelling in the region of the lachrymal sac; perhaps the swelling may be painful and tense, and often as big as a walnut. Sometimes when pressure is made on this swelling the contents consisting of pus and mucus can be forced out through the puncta—or more rarely through the nose. The immediate cause of this condition is some obstruction of the nasal duct. The tears can no longer find an exit into the nose, and begin to accumulate in the sac, which becomes more and more distended. The tears soon become decomposed and start an irritation of the mucous membrane lining the sac, which then undergoes an inflammation throwing out pyoid secretion which mixes with the tears in the sac. The contents then grow more turbid and resemble pus.

Constrictions of the nasal duct may come from inflammation of the mucous membrane in the nose, simple chronic catarrh, or from a scrofulous or syphilitic origin. The swelling of the mucous membrane may extend by continuity to the mucous membrane of the duct. In the ordinary forms of ozena there is no swelling, but cicatricial contraction of the nasal mucous membrane, which may lead to the constriction of the inferior orifice of the duct. Ulcers of the mucous membrane and polypi are also causes of obstruction at the nasal orifice.

The course is long, often extending years if nothing is done for it. The secretion that at first was purulent becomes mucous and viscid, the mucous membrane may atrophy and the distended sac contain nothing but tears, but the epiphora still remains.

A person suffering from this chronic form may have an acute attack of inflammation suddenly develop. The skin over the sac becomes reddened and greatly swollen, the swelling often extending to the lids, and to the conjunctiva which may become chemotic. There is generally a great deal of pain, so much so that the patient is deprived of sleep. After a few days the skin at the apex shows a yellowish point and becomes perforated, the pus discharges and the swelling gradually disappears. Afterwards pus followed by mucus, and later tears are discharged. As long as this fistula remains open the patient is safe from another attack, but if it closes up a recurrence may ensue.

In the treatment of the milder forms in which epiphora is the most annoying symptom we should always examine the nose, and if any trouble is found there it should be treated. Often uncorrected errors of refraction are a cause, and should also be carefully looked after. Suitable washes where there is only an irritation of the lachrymal tract are often of great benefit.

The large majority of cases are only benefited by operative treatment, and this, in my opinion, is best accomplished by a complete division of the stricture and the use of large probes. In all cases, acute or chronic, I operate as soon as it is possible to pass my knife straight into the sac, that is, if the parts are not too much displaced by the swelling. If there is too much swelling I use hot applications, and wait for a chance to let the pus out. Generally a day or two after this is done the duct is in such a condition that a proper opening can be made. I always use a Weber knife with a long shank, and Theobald's probes. I make the incision in the ordinary way. I insert the probe-pointed end in the lower punctum with the knife

¹ Read before the Massachusetts Medical Society, June 8, 1897, and recommended for publication by the Society.

straight up, then depressing the knife down and out 90 degrees, and with the cutting edge turned slightly toward the eyeball, I push forward until the point touches the inner wall of the sac. I then bring my knife up perpendicular, and holding it lightly but firmly, pointing slightly backward and outward, push it straight down until it reaches the floor of the nose. I then pull it back, turn it a quarter of a circle and push it down again, withdraw it nearly again and turn it a quarter more and cut again, and still once more, making four cuts down through the stricture. This is all done very quickly. I then pass the largest Theobald probe I can into the nose (generally a 12 or 14), bandage up the patient's eye and send him home, giving him a wash of boracic acid, dilute hydrocyanic acid, cocaine and water, to use freely. I probe the two following days with the same sized probe I used on the day of the operation. Then I probe every other day for the next week, then twice the next week, and once the next; then again in two weeks. This generally suffices although not always. If patients need any more probings, I am very apt to use a slightly smaller probe, especially if they have been three or four weeks without having any probe passed. I *never* leave the probe in. I pass it and immediately withdraw it.

In making the incisions in the stricture and dilating, we have a certain amount of exudation thrown out into the cuts; this cut is again forced open the next day, and at each succeeding probing, and another chance for a new exudate given. In this way when we are done with our probing, we have or should have four cicatrices that retract rather than contract, and leave us an opening through which tears can pass. The extended sac will generally diminish and return to nearly its normal size, or near enough to cause no further trouble.

When we have a largely distended sac that will not contract, there is ordinarily nothing left but extirpation or cauterization. No one will claim that all cases of epiphora or lachrymal obstruction can be cured. We have too many that are apparently just as badly off when they leave off treatment as when they began. I certainly think that the free incision of the stricture and the proper probing afterwards will do more in my hands than any other method that I have used.

Clinical Department.

A CASE OF DOUBLE OVARIOTOMY DURING PREGNANCY.¹

LABOR COMPLICATED BY UTERINE INERTIA.

BY R. A. KINGMAN, M.D., BOSTON.

THE case which I am about to report to you may well be considered ancient history, having occurred several years ago, and yet it presents several interesting and suggestive features, which render it worthy of record.

Lucy H., married, thirty-seven years of age, presented herself for examination at the Boston Dispensary in May, 1892. She stated that some eight or nine months previous she had consulted a prominent member of this Society who told her she had an ova-

rian tumor, but that there was no necessity for operation at that time.

Now, however, she had reason to believe she was pregnant, and for that reason sought further advice. The data were not conclusive; but it seemed probable that the pregnancy was of about two and one-half months' duration.

Examination showed a tumor of typical ovarian characteristics, extending to the lower ribs on the left. It was of a size corresponding to six or seven months' pregnancy. At its upper and left-hand margin there was a hard mass, the size of a man's hand, of limited mobility. At no point was pain elicited on palpation.

Crowded into the pelvis was a separate elastic tumor, which just filled the pelvic cavity. This was apparently continuous with the cervix, and was assumed to be the pregnant uterus.

May 30th the patient entered St. Elizabeth's Hospital, and was operated on June 1st. A median incision disclosed a cyst of the left ovary, which contained over a quart of clear fluid. The hard portion noticed at the upper left-hand margin proved to be a papillary mass which was adherent to parietes and viscera, but was easily separated from them.

The only unusual condition noted in consequence of the pregnancy was the extreme vascularity of the pedicle, which consisted of the whole breadth of the broad ligament. It seemed one mass of dilated, tortuous veins. This was ligated with pedicle silk, the cobbler's stitch being used.

The toilet of the peritonemum was being hastily performed, the desire being to expose the uterus as little as possible, when a second globular tumor was felt beneath the uterus. For a moment, remembering the diagnosis as made at the previous examination, I thought the lower tumor might be the pregnant uterus, the upper one being the bladder. This, of course, was a foolish thought, only excusable in view of my somewhat limited experience; and yet the two tumors were exactly in the median line, of the same size, and feeling almost identical to the fingers. Ocular inspection instantly showed that the lower tumor was another cyst, developed from the right ovary.

This was removed in the same manner, the same varicose condition being present.

The uterus was of the size of a very large navel orange.

The recovery of the patient was as comfortable and uneventful as could be wished, there being almost no shock and never any symptom of threatening miscarriage.

In order to follow this case to its conclusion I attended Mrs. H. in her confinement, which occurred December 17th, six and a half months after the laparotomy. Her pregnancy had been a comfortable one, and the scar had yielded but little.

I was called to her after she had been in labor about three hours, the pains at no time being strong. I found the abdomen no larger than it commonly is at eight months and on palpation noticed that the uterine wall was very thin, the fetal parts being felt with the greatest ease. The presentation was by the head, O. L. A., the os being almost fully dilated.

As I observed them, the pains were feeble and ineffectual, though the patient made great outcry with each one. They were regular and of proper frequency, but produced no result. The patient soon became unmanage-

¹ Read before the Obstetrical Section of the Suffolk District Medical Society, February 24, 1897.

able, throwing herself about the bed and refusing utterly to make any effort at expulsion. Small doses of ether were given with a few of the pains, but with the effect only of making her happy and comfortable. No progress being made and none in prospect, the head being in the pelvis and so small that a single strong expulsive effort would have expelled it, I gave a very little ether and extracted the child with forceps. For this manoeuvre only one hand was used, and no appreciable effort was required.

The uterus was held continuously by myself, and the placenta was easily expressed after an interval of twenty minutes.

Immediately following the placenta there came a severe hemorrhage. The uterus refused to contract; in fact remained so soft and flabby that it could not be wholly compressed between the hand in the vagina and the external hand. Add to this the lack of a competent nurse and the fact that the patient persisted in trying to pull my hand away from the abdomen, and it will be seen that I had to work under difficulties.

For a time I held the flood in check by seizing the cervix in my fingers and compressing it firmly, at the same time jamming cervix and fundus together. After a time, however, the fingers would tire, and then the blood would spurt as badly as ever. Ice and hot water had been used in the mean time under my direction.

At this juncture it occurred to me to try vinegar, of which I had often heard but which I had never used. A large pledget of absorbent cotton wet in vinegar was accordingly thrust into the uterine cavity and compression used as before. The result was instantaneous. There was no more hemorrhage, and the uterus contracted so that I felt safe in removing the cotton at the end of half an hour.

This patient had a normal convalescence.

The baby was not weighed, but was certainly not over four and a half pounds. It grew rapidly, and at one year weighed about forty pounds.

The points of interest which I would briefly mention are as follows:

(1) The dangerous advice given by the first physician consulted. The impression is far too common that an ovarian tumor, being a benign growth, may be neglected.

(2) The occurrence of pregnancy in spite of the advanced cystic disease of both ovaries.

(3) The easy convalescence after operation, demonstrating the tolerance of the pregnant uterus.

(4) The evidence against the Tyler-Smith theory of the determining cause of labor. This theory supposes that labor comes on in consequence of the increased congestion and nervous disturbance accompanying the recurring menstrual epoch, though why the ninth or tenth rather than the eighth or eleventh is not stated. One of my friends called my attention to this so-called ovarian theory, and jokingly suggested that the ovaries being removed and the cause of the menstrual nixus being therefore absent, I might find that labor would be indefinitely postponed. As a matter of fact, labor came on just when it was expected.

(5) The lack of development of the uterus and the small size of the child. Were these conditions due to the absence of the ovaries or to the cutting off of a part of the blood-supply? I am inclined to believe

that the presence or absence of the ovaries has little influence upon the development of the pregnant uterus. The ovarian artery, however, cannot but be an important factor, it acquiring the size of three to four millimetres in diameter at the close of the gestation period, being in fact only a trifle smaller than the uterine artery. The ovarian vein is said to develop until it exceeds the uterine vein in size, equalling the internal or external iliac. Complete closure of this portion of the uterine circulation must of necessity interfere to some extent with the development of the uterus and its contents.

(6) The resultant post-partum hemorrhage and the simple means by which it was controlled. Packing the uterus with iodoform gauze might have produced the same result and been a more surgical procedure, but it would have been less simple in its application, would have required more time, and it presupposes the possession of the gauze and sterilized instruments for its insertion. Vinegar is always obtainable; and in the two cases in which I have used it, the effect has been all that could be desired, and no evil after-result has been noted.

A CASE OF OVARIOTOMY DURING PREGNANCY.¹

PATIENT FIVE MONTHS PREGNANT; REPLACEMENT OF RETRODEVIIATED INCARCERATED FUNDUS; NORMAL LABOR AT TERM.

BY W. L. BURRAGE, M.D., BOSTON.

D. H., age twenty-six; married two years; one child, thirteen months; no abortions. First seen October 25, 1893. Had an attack of flowing in August, 1892, two weeks after her baby was born and had not flowed since except that she had a normal menstruation of five days, May 10, 1893. Was in labor five days; ether and forceps used; baby weighed ten pounds and a quarter; in bed three weeks after labor; nursed child. She noticed prolapse of the parts at the vulva as soon as she got up, and the condition persisted in spite of treatment by her doctor with packing and a ring pessary.

Early in September she thought she might be pregnant, being unable to eat her usual articles of diet, and having cravings as at her previous pregnancy. Accordingly she weaned her child. She noticed at this time that her womb came outside the body; and she suffered with dysuria and was unable to sit or walk with comfort. She also suffered from constipation and from pain above the pubes, that had been increasing in severity ever since. She complained chiefly of this pain when I saw her at the Carney Hospital, October 25, 1893. I found the cervix uteri enormously elongated, with as much as an inch and a half projecting from the vulva; deep laceration of the perineum; pelvis filled with a semi-solid tumor, apparently the retroflexed uterus about four and a half months pregnant. Above and on the right, lying on the pelvic brim, was a tumor of indefinite outline, the size of a cocoanut.

By forcible bimanual manipulation I was able to partly dislodge the pelvic tumor, and the patient was kept in bed until six days later, October 31st, when she was given ether and a thorough examination made. Dr. F. W. Johnson kindly saw the case with me in consultation. We found the fundus uteri out of the pelvis, and the cervix high; and we also made out a

¹ Read before the Obstetrical Section of the Suffolk District Medical Society, February 24, 1897.

cystic tumor apparently of the right ovary, the size of a coconut.

On account of the limited space in the abdomen, and the rapidly growing uterus, it seemed best to remove the cyst by abdominal section. Having allowed a sufficient time to elapse after the etherization to prevent all fear of miscarriage, I performed ovariectomy November 10, 1893.

The incision was in the median line, three and a half inches in length, its upper end being half an inch above the umbilicus. The pregnant fundus presented in the wound, and above it on the right side a bluish, thin-walled ovarian cyst that was not fully distended with a fluid of the color and consistency of mucilage. Attached to the main cyst, which contained three quarts of fluid, was a bunch of smaller cysts with colloid contents, the largest being the size of a small orange. There were a few slight adhesions to the anterior abdominal walls.

The tumor was tapped, delivered and tied off in the usual manner. The pedicle was very vascular. I noted that the elongated Fallopian tube was not appreciably enlarged in its diameter, but that the ovarian ligament was much hypertrophied throughout its length. The left ovary was normal with the exception of a few small cysts in its substance, the largest the size of a pea. These were punctured.

The convalescence was uneventful. The wound healed by first intention, and being situated so high in the abdomen no abdominal supporter seemed to be indicated. The patient felt life on the day following the operation; and, as I think I have failed to note, she had felt fetal movements for three or four days before the operation. The temperature was normal, and the patient was up in three weeks.

March 17, 1894, or 280 days from June 10, 1893, she was delivered by Dr. J. L. Morse of a living male child weighing six pounds. The labor and convalescence were normal. Dr. Morse measured her pelvis and reported it as being slightly justo-minor.

Mrs. H. presented herself with her baby at my office, May 9, 1894. She had then a firm cicatrix, a quarter of an inch wide, in the abdominal wall. The uterus was of normal size, but low in the pelvis, and there was extensive injury of the pelvic floor and perineum. She was advised to have these injuries repaired. The mother and child were in perfect health.

Medical Progress.

REPORT ON DISEASES OF CHILDREN.

BY T. M. ROTCH, M.D., AND A. H. WENTWORTH, M.D.

BATHS IN SCARLET FEVER.¹

DR. SCHILL (Wiesbaden) reports his and Dr. Schellenberg's results in the treatment of 110 cases of scarlet fever by means of warm baths; 63 of the cases were treated by Dr. Schill since 1892, and 47 cases were treated by Dr. Schellenberg since 1893.

The baths were given twice a day during the first week, and once a day afterward. The temperature of the water was 28° R., and the duration of each bath was ten minutes. Only one of Dr. Schill's cases was severe. This case was complicated with a phlegmou-

ous inflammation of the submaxillary gland and with a nephritis. Of the 47 cases treated by Dr. Schellenberg, five could not be bathed, and one of these cases developed a nephritis. The course of the disease in the remaining cases was mild. Neither nephritis nor albuminuria occurred in any of them. The author alludes to the disturbances of function produced in the skin by the dermatitis of scarlet fever and to the importance of assisting these functions under such conditions.

Reference is made to the article of Ssokolow, entitled "The Perspiration of Children under Physiological and Pathological Conditions," in which the author says: "The perspiration is markedly diminished in scarlet fever. The immediate result of this diminution is to cause albuminuria from disturbance of function in the kidneys. Varnishing the skin with various substances almost invariably produces albuminuria. The application of vaseline over the body diminishes perspiration one-half." Greasing the skin is therefore harmful.

With the exception of the fingers, desquamation was not observed in the cases treated by baths. The epidermis is gradually removed by the daily bathing, and the scarlet-fever toxin has a chance to escape through the sweat glands. In this way the author accounts for the absence of complications and the mild course of the disease.

COR BOVINUM IN AN INFANT.²

M. Hauser exhibited an hypertrophied heart from an infant of eleven months. At the time of its death the child had had pertussis for five months and was very anemic. During the last five weeks of its life it suffered from dyspnea, but the author had not detected any organic malady which accounted for it. At the autopsy, the heart was found to be much enlarged; the walls of both ventricles were hypertrophied and the cavities dilated; there was passive congestion of the abdominal viscera. The only cause which could be detected for the above-mentioned conditions was the increased blood-pressure caused by the violent and prolonged cough.

ON THE EMPLOYMENT OF THYROIDIN IN CHILDHOOD.⁴

Alfred Dobrowsky considers briefly the work of other men in this direction, and then gives the results of his treatment of 30 infants and children with thyroidin. The cases were as follows: nine cases of parenchymatous goitre; eight cases of prurigo; one case of obesity; and 12 cases of idiocy and cretinism. Merck's tablets of thyroidin were used, each tablet of which contained 0.35 of thyroidin. Infants under two years of age were given from one-half to one tablet daily during the first week, and from one to two tablets daily afterwards. Older children were given one to two tablets daily during the first week, and from three to four tablets daily afterwards. The treatment was continued for from three weeks to three or four months. The patient remained under observation after the treatment was suspended. The article concludes with the following summary:

(1) Merck's preparation of dried thyroidin produces a loss of weight in both healthy and sick chil-

² Archiv. f. Kinderheilk., xiv, 255.

³ Soc. Clinique de Londres, 8 Janvier, 1897; Rev. Mens. des Maladies de l'Enfance, Avril, 1897.

⁴ Archiv. f. Kinderheilk., B. xxi, S. 51, 1896.

¹ Jahrbuch f. Kinderheilk., xliii, S. 260, 1896.

dren irrespective of special diet. The loss of weight reaches its maximum in about four weeks, after this time little or no additional loss of weight occurs, in spite of the continuance of the treatment. The loss of weight varied from 0.5 to 3.5 kilog. (1.1 to 7.7 lbs.). A gain in weight begins in from one to two weeks after the treatment has been discontinued.

(2) In case of parenchymatous goitre, thyroïdin produces a marked diminution in the size of the gland. The effects are observed in two or three days, and the maximum result is obtained in about three weeks. Further treatment merely hinders the recurrence of the swelling. Measurements of the neck showed a diminution of from one to four centimetres in circumference.

(3) An increase in the rapidity of the heart's action occurred in all cases soon after beginning the treatment. The tachycardia was not accompanied by subjective symptoms of palpitation and ceased as soon as the treatment was discontinued.

(4) A marked improvement occurred in all the cases of prurigo a few days after the treatment was begun. The itching ceased and the accompanying eczema disappeared. The skin became softer and moister and the children slept better and improved in their general condition. Relapses occurred in all cases in from one to thirteen weeks after the treatment was stopped. A renewal of the treatment produced the same temporary improvement as before.

(5) Practically negative results were obtained in the treatment of idiocy and cretinism. Of the twelve cases thus treated, two only showed a slight improvement in their ability to maintain an upright position and in one case slight improvement in the intelligence.

(6) The author was unable to detect any noteworthy effect produced upon the blood by the treatment.

(7) Increased thirst and diuresis were observed in almost every case. The amount of phosphorus was increased in the urine. Indican was constantly present in the urine and oftentimes increased. Albuminuria and glycosuria did not occur.

(8) The dried thyroïdin prepared by E. Merck was found to be reliable.

(9) The cautious employment of the remedy, beginning with small doses and increasing them gradually, convinced the author that the treatment was not dangerous. It is necessary to watch the patients carefully to detect idiosyncrasies and if the heart's action becomes irregular the treatment should be suspended.

(10) Thyroïdin is a reliable, but not radical, remedy in the treatment of parenchymatous goitre which has not undergone secondary changes. It is of value in the treatment of prurigo and obesity. It appears to be of little value in case of idiocy. It is of great value in cases in which from idiosyncrasy the treatment by means of iodine is impossible.

(11) Cessation of treatment is followed by relapse.

THE PRESENCE OF DIPHTHERIA BACILLI IN THE THROATS OF HOSPITAL PATIENTS.⁶

E. Müller was led by the occurrence of several cases of diphtheria in one of the wards of Professor Heubner to make systematic bacteriological examinations of the secretions from the throats of all the children who were admitted into this ward. Daily exam-

inations were made of all the patients in this ward during a period of five months. The total number of cases examined was 100, and of this number, 24 gave positive results. None of the cases showed any traces of angina or stomatitis. Diphtheria bacilli were found in the throats of four of the eight children who were in the ward at the time when the examinations were begun. Positive cultures were obtained from six children at the time of their entrance into the hospital. In the remaining 14 cases, positive cultures were obtained after the patients had been for some time in the ward, the length of time varying from several days to several weeks. In some of these cases the patients occupied beds next to those in which were patients from whom positive cultures had been obtained. The length of time during which positive cultures were obtained in these cases varied from several days to several weeks. There were neither general nor local symptoms in any of the 24 cases at any time, although in a number of cases the bacilli were very virulent. Inoculation experiments were made from 12 cases; of these six proved fatal to animals in from twenty-four to forty-eight hours; the remaining six were less virulent.

Of the six cases in which the cultures were positive at the time of entrance into the hospital, one came from a family in which there had been several cases of diphtheria five weeks previously; two other cases were transferred from the ward for measles; of the remaining three no history could be obtained of contact with diphtheria.

ARRHYTHMIC ACTION OF THE HEART IN CHILDHOOD.⁶

O. Heubner's observations are confined to the occurrence of arrhythmic heart's action in children, exclusive of cases of organic heart disease and tubercular meningitis.

(1) As a manifestation of the toxic action of drugs this symptom occurred in one case of stramonium poisoning; not infrequently in cases of heart disease treated with digitalis; and in one case of afebrile appendicitis treated with large doses of opium.

(2) In dyspeptic conditions, possibly due to auto-intoxication from the intestines. In one such case the arrhythmic action of the heart formed one of a severe group of nervous symptoms, consisting of retraction of the neck, stupor, vomiting and fever. The attack ended in recovery after four days and with beginning convalescence a large quantity of acetone was present in the urine. In a second case of auto-intoxication, the same symptoms occurred together with convulsions. A strong odor of acetone was apparent in this case.

(3) In diseases of the abdominal organs, especially those accompanied by vomiting, in which, however, auto-intoxication was not evident.

(4) In the course of infectious diseases, especially during the stage of convalescence. One such case was that of a ten months old infant in whom the arrhythmic heart's action formed one of the symptoms of an obscure and severe infectious disease, possibly typhoid. Under this heading are included the cases of arrhythmic heart's action occurring after diphtheria, due to the action of toxin on the heart's muscle; less frequently cases of scarlet fever, with or without nephritis, but without organic lesion of the heart; and in some cases of scarlet fever in which the symptoms were by no means severe. The occurrence of this symptom after

⁶ Jahrbuch f. Kinderheilk., B. xliii, S. 51, 1896; Rev. Mens. des Maladies de l'Enfance, Février, 1897.

⁶ Zeitsch. f. klin. Med., 26 Bd, 5 u 6 H; Jahrbuch f. Kinderheilk., B. xliii, S 355.

scarlet fever, measles, pneumonia and typhoid is much less grave than when it occurs in diphtheria.

(5) In anemic and nervous children, arhythmic action of the heart is not uncommon and has at times led to an incorrect diagnosis of tubercular meningitis.

Heubner refers also to the cases of arhythmic heart's action occurring in pale, rapidly growing children at the time of puberty, attributed by Kressig to the disproportion existing between the size of the heart and the size of the arteries, but says that he has not observed them.

(6) Arhythmic heart's action coincident with the presence of intestinal parasites.

(7) Arhythmic heart's action following psychical disturbances; during sleep (Czerny); following exposure to cold after a warm bath (Löschner); and probably of reflex origin.

(8) A so-called idiopathic arhythmic action described by Da Costa, which occurs in children from three to six years of age, oftentimes in several children of the same family. The symptom becomes more evident after deep breathing, and may be the only abnormality presented by the child.

How the arhythmic action of the heart is produced is not always apparent. In some cases it is the result of nervous influence. In tubercular meningitis it may be due to the pressure produced by an increased quantity of fluid in the ventricles acting upon the vagus at its place of origin in the medulla. In other cases it is caused by reflex irritation of the vagus produced through the medium of other nerves, such as the splanchnic.

In cases of poisoning the arhythmic action of the heart may be caused by the direct action of the poison in the heart's muscle, or by its direct or reflex action in the vagus at its place of origin. Occurring during or after infectious diseases, it is presumably due to the direct action of the toxins in the heart's muscle. The occurrence of arhythmic heart's action as a result of direct irritation of the vagus nerve itself is very rare. The cause or causes for its occurrence in anemic and rapidly growing children have not been satisfactorily explained.

It may be said that, as a rule, the duration of arhythmic heart's action in children is temporary, and that the treatment is dependent upon the cause. Da Costa recommends a certain amount of daily exercise, which should be carefully supervised to avoid overexertion, and which should be gradually increased; small quantities of food should be given frequently; and sea-bathing for the cases in which the symptom is habitual.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. THE SECTION FOR OBSTETRICS AND DISEASES OF WOMEN.

C. H. HARE, M.D., SECRETARY.

REGULAR meeting, Wednesday, February 24, 1897,
DR. F. W. JOHNSON in the chair.

PATHOLOGICAL SPECIMENS.

DR. E. GARCEAU showed two kidneys which were removed for suppurative disease.

DR. S. E. PALMER exhibited specimens from a

patient operated on at Carney Hospital in the service of Dr. Johnson.

K. L., domestic, single, age thirty-five. Family history good.

Patient says she had malaria two years ago, but with that exception was well until last spring, when she was troubled by frequent micturition, with some pain. In July of 1896, backache with sensation of weight in epigastrium. These three symptoms (frequent urination, backache and weight) increased until she was forced to consult a physician, which she did at the Boston Dispensary. He made a diagnosis of tumor in the pelvis, and sent her to the hospital. Before the operation temperature and pulse varied between 99 and 100. She entered the hospital February 8, 1897.

An incision about 11 cm. long being made by me in the median line, two large, whitish tumors were soon seen. These proved to be dilated tubes, adherent everywhere to the intestine, particularly to the rectum. The uterus was rather small and bladder adherent. These tubes, when removed, together weighed a pound. That on the right was the smaller, and, in turn, adhered to a mass which proved to be an encysted peritonitis lying on the dilated left broad ligament, which included an intra-ligamentous cyst. This was enucleated with the cyst wall and the broad ligament sewed up (the tubes having been first removed) with shoemakers' stitch, and fortunately without breaking.

I have brought them to show to-night, although somewhat shrunken, and therefore we have no pathological report. The rough sketch gives the size by measurement and the approximate shape.

The recovery has been almost without event. The temperature and pulse reached 100 two days after the operation, but soon fell. With urination there has been trouble—retention and some pain; but that is now relieved.

DR. E. W. CUSHING: This is a fibroid I removed yesterday. It is interesting, from one point, as showing how the fibroid started from one side of the uterus and how the tube starting from the lower part of the mass is extended clear around the tumor to the other side where it was cut off, and where it was strongly adherent to the side of the pelvis far down by the rectum. The tumor in growing on the left side had grown into the broad ligament so that the bowel was apparently adherent to, but really inserted into the peritoneum. This is a little bit of appendix epiploicum which was in apparently intimate union with the tumor. The growth could have been removed, I think, leaving the uterus, but I did not think it wise to do it. The other tube and ovary were diseased, firmly adherent, so it was impossible to remove the growth until clamps had been applied, so as to remove the tumor and uterus, leaving in place the tubes and ovaries which were removed afterwards. In removing it it appeared that the small mass was an outgrowth from the tumor. It was not until afterwards that it was shown to be the uterus. I bring the specimen as showing how many of these fibroids would be susceptible to the treatment suggested the last time, of getting it out through the vagina.

DR. RICHARDSON: This specimen of a hydrocele of the canal of Nück is rather unusual. The woman had apparently a left inguinal hernia. There was the history of hernia—a tumor which she said appeared suddenly on exertion, and which varied in size,

being sometimes larger and sometimes smaller, according to the position of the body. The tumor evidently contained fluid. I thought it either a hernia with incarcerated omentum and effused fluid, a rapidly growing soft sarcoma, or a hydrocele of the canal of Nück. I removed the tumor unbroken. There was a slight communication between the abdominal cavity and the hydrocele; yet it was impossible to force the contents of the hydrocele into the peritoneal cavity either before or during the operation.

DR. KINGMAN read a paper on

A CASE OF DOUBLE OVARIOTOMY DURING PREGNANCY.¹

DR. BURRAGE also reported

A CASE OF OVARIOTOMY DURING PREGNANCY.²

One or two observations come to me as a result of this experience and of hearing Dr. Kingman's paper. The question of operation in cases of pregnancy complicated by ovarian tumor comes up. In looking over the literature at the time I operated, I found a great many cases reported, and that the opinion seemed to prevail that the cause of miscarriage in these cases was the sepsis and not the operative interference; and I think it is held by most authorities at the present time that if the operation is aseptic, there need be very little danger. The condition of the tumor in my case was interesting. The cyst was not full; the walls were flabby. Whether that was an effort of nature to absorb some of the fluid it is impossible to say. We occasionally find tumors in which the walls are in this condition, and that has occurred to me as a possible explanation. With such a thin-walled cyst the danger of rupture as pregnancy progresses would be a serious one. We have to bear in mind that we know nothing of the nature of the contents of a cyst, the thickness of its walls or the chances of its rupture during labor or of its causing miscarriages or dystocia. On the chances it seems to me it would be far wiser to operate on cases where we can diagnose an ovarian cyst of any considerable size during pregnancy rather than to wait. The size of the child interested me. The patient had had a labor before this one in which the child weighed ten and a quarter pounds; and, other things being equal, this child's weight should have borne some relation to that of the previous one. We must take into account that the uterus in this case was wedged into the pelvis and its circulation interfered with, but it brings up the point how much influence cutting off the ovarian circulation by an operation had to do with the future development of the child. My case was operated on a little later in pregnancy than Dr. Kingman's, and it would be interesting also to work out the effect that the period of operation and the unilateral or bilateral character of it has on the blood-supply to the uterus and the development of the fetus.

DR. CUSHING: I have two cases bearing somewhat on this subject.

Some years ago I had a patient with an ovarian tumor, and she was six months along in pregnancy. The tumor was a tumor of the broad ligament, but it was about the size of a two-quart jar. It was growing rapidly, and as she was beginning to suffer I operated. There was no especial difficulty about the

operation except the question of avoiding hemorrhage. I was astonished at the size of the veins on the side where the tumor was; the ovarian artery was greatly enlarged, but the veins of the pampiniform plexus were something wonderful. There was no particular hemorrhage, recovery was prompt, and the subsequent delivery was normal.

I had another case more curious, not an ovarian tumor. Three years ago I was called in consultation by Dr. Cumston for a lady who was having hemorrhages and high fever and had had a chill. There had been some question of pregnancy; she had skipped one term, was somewhat nauseated. There was a mass on the left side. It was impossible to make an exact diagnosis. A provisional diagnosis was made of extra-uterine pregnancy or salpingitis. The patient was dangerously ill. Operation followed and the left ovary and tube were removed in the presence and with the assistance of Drs. Cumston and Derby. The tube contained pus and the adhesions showed a state of inflammation around it. The right tube was occluded, but the right ovary was not removed; only the occluded end of the tube, and the stump was closed lightly with fine catgut with the hope that perhaps there might be a useful tube saved. It is well known that several cases of pregnancy have occurred in women who have had one tube and part of the other removed. The uterus was about the size of a uterus at two months. It was supposed that probably that was owing to inflammation, and nothing was done to explore the uterine cavity. The patient made a good recovery. Two months afterwards the woman aborted and there was great wonderment as to whether the diagnosis was correct and whether the operation was proper, and why we did not pass a sound, etc. The operation was done for urgent symptoms; the uterus was not explored. It only shows how independent in the first three months the fetus in its sac is of a very considerable portion of the uterus, which may have hemorrhages, and may endure a sound being passed without provoking miscarriage. It was known there was gonorrhea in the husband, who was under treatment at the time for gonorrheal ophthalmia, and was a very sick man, with gonorrhea undoubtedly as the cause of it. It was easily inferred that the gonorrheal inflammation was at the root of the salpingitis; and the question naturally arises how pregnancy could have occurred with one tube actively inflamed and pus in it and the other tube occluded. It presents rather a curious problem, but it is clear that the occlusion of the tube and the violent symptoms occurred subsequent to conception.

In regard to operation during pregnancy it seems to me we can hardly lay down a hard-and-fast rule. Where the tumor is small, free, rising in the pelvis above the uterus, not growing very rapidly, I think there is much to be said in favor of waiting, because it is not very likely to cause trouble. Where the tumor is in such position as not to rise freely, the uterus wedged in any way, more or less adhesions binding down the uterus, and liable to cause miscarriage or rupture, I think operation is desirable and if rightly done, not particularly liable to interfere with the pregnancy. The question has been raised whether it is not justifiable to provoke abortion first and remove the tumor leisurely afterwards. I do not think that it is necessary or justifiable. There is nothing to show an abortion occurring a few days or a week

¹ See page 103 of the Journal.

² See page 104 of the Journal.

after an operation will seriously aggravate the condition of the woman or make the result of the operation worse.

DR. M. STORER: I am glad to hear Dr. Burrage take such strong ground about operating. Gordon recently collected 200 cases of ovariectomy during pregnancy, with a mortality of only three per cent. Ols-hausen and Dsirne have shown that cases of ovarian tumor which give symptoms enough to be diagnosed have, unoperated, a maternal mortality of about 25 per cent., and nearly one-half of the children are lost, while with early operation 80 per cent. are saved. If by operation we get such brilliant results, it seems to me that the rights of both mother and child demand it. The months most favorable for operation are for the mother the third and fourth, and for the child the second and third.

Should pregnancy be passed in safety the mother's danger is by no means over. An ovarian cyst is liable to many accidents during and immediately following labor. Mangiagalli, in 150 ovariectomies, had 11 emergency of operations after labor for torsions, ruptures, etc.

There is an interesting question Dr. Kingman did not speak of, that of the growth of these cysts during pregnancy. There are two views: one, that owing to increased vascularity, the cyst tends to increase; the other, that, owing to functional inactivity of the ovaries during pregnancy, cysts tend to remain quiescent. Wells had a case of dermoid which during a number of pregnancies decreased regularly, and increased as regularly during the intervals. In spite of a few observations like this, I think most writers now hold that ovarian cysts do tend to grow during pregnancy; and I find in this an added argument for operation.

DR. RICHARDSON: I should like to speak of one case of ovarian cyst. A young married woman had, in the region of the right kidney, a tumor about the size of a child's head; low down in the abdomen, rather to the left, was another similar in size and feel. I removed the right ovarian cyst without difficulty; and proceeding to tap the left, I found that I was trying to tap a pregnant uterus. Fortunately the trocar was dull and the tumor thick-walled. The trocar did not penetrate the uterus. The woman recovered, went to term, and was successfully delivered. I have published this case in full in the *Boston Medical and Surgical Journal*.

DR. KINGMAN: Speaking about the necessity of operating rather than trusting to time in these cases, I want to speak of the danger of torsion of the pedicle following delivery in cases of ovarian cystoma. I believe that is recognized as quite a common occurrence. I saw one such case a year ago, in which a tumor the size of the uterus at term had apparently escaped attention, but after delivery, it fell into the position before occupied by the pregnant uterus with twist of the pedicle and the usual symptoms. The patient when I saw her had gangrene of the omentum. I believe it is safer to operate during pregnancy than to wait until after delivery, thus incurring the danger of torsion.

DR. GARCEAU read a paper on

SOME CASES OF CYSTITIS IN WOMEN.³

DR. CHADWICK: It is hard to pick out the points to allude to in this paper; but the series of cases is exceedingly interesting, showing how much can be ac-

complished by modern surgery in a class of cases formerly considered incurable. Two of them were patients whom I sent to Dr. Garceau — the first case of tubercular disease of the kidney, and the protracted twenty years' cystitis. In both of them the ordinary old-fashioned treatment had failed. I was glad to hear Dr. Garceau make at the end some discrimination between ordinary cases of cystitis which do not need the cystoscope, or to have the ureters catheterized. I think it is very important to bear that in mind; with the great advance which these two measures give us it is very natural to apply them to every case. It is not necessary, and it is harmful. I say harmful, because I have seen a certain amount of cystitis set up, and lasting several months, due to the use of the cystoscope in a woman who had not had cystitis before. At the same time that I sent these two cases to Dr. Garceau I was treating half-a-dozen others, all of whom were cured by me. These two cases I could not cure, and I sent them to him, and he has pretty nearly cured them. The result of operations for tuberculosis of the kidney I think is not fully established. In the first case reported the result has been admirable so far. The improvement of the girl has been very great and worth the operation. I do not feel sure as to the future. The risks are considerable. The immediate mortality of the operation seems to be nearly one out of three, according to the statistics compiled. I fancy the very best operators recently have much better results than that, but I have seen recently published statistics of 130 or 140 cases in which 39 per cent. died; I think that is greater than the operation has now.

There are dangers in the first place from shock. The danger from shock varies according to whether the lumbar or abdominal operation is done, though I do not think it is clearly established why the risk from shock is so great. I remember some years ago it being alluded to by Dr. John Homans, that a number of cases had had not merely death from shock, but sudden tremendous diminution in the secretion of urine in the first twenty-four hours after operation. It is not the extirpation of the kidney that diminishes the secretion of urine, because in a case about that time I removed a sarcomatous tumor as big as my two fists and left the kidney, yet the same sudden arrest of secretion took place. The shock seems to be reflex and to have nothing to do with the arrested secretion.

How far the lumbar operation is going to satisfy us I do not know as yet. It seems to me there is danger that the infection will have reached the ureter, which cannot be removed by the lumbar incision. If we turn to the abdominal operation, the danger from shock is two or three times greater than by the lumbar operation, and I think the percentage of mortality is much greater; but as far as I can see and as far as I have looked into the subject, the benefits thus far are fully established.

DR. RICHARDSON: There are two points in this paper which interest me particularly; the first negatively, because I have never seen in cases of pyelonephritis of tubercular or calcareous origin any prominence in the bladder symptoms. The very thorough and scientific methods used by Dr. Garceau in determining the condition of the two kidneys is very commendable; if employed in every case, it would give us information about the comparative condition of the kidneys by which we could avoid some of the errors of

³ See page 97 of the Journal.

renal surgery. I can bring to this discussion but one case of tuberculosis of the kidney, and in that case there were no bladder symptoms whatever. The patient, a woman of about forty-five, had symptoms referable chiefly to the Fallopian tubes. I opened the abdomen, and found both enlarged and tubercular. An enlargement of the left kidney had been previously detected. At the first operation the kidney was examined, and found to be much enlarged and apparently cystic. The symptoms reappeared soon after the operation. I thereupon explored, and removed a large tubercular left kidney. The tuberculosis was found to extend far down the ureter. I dissected it nearly to the bladder, where I cut it off. There were no bladder symptoms. This patient died of pulmonary tuberculosis within two or three months of the nephrectomy.

The reader's paper brings out in a strong light the importance of considering the kidneys in all cases of obstinate cystitis. The cases which I have seen, however, have been those accompanied by lesion of the kidney rather than of the bladder.

In connection with this subject I am interested in what has been said about the dangers of nephrectomy. By judicious selection of cases I am sure that the mortality in nephrectomies will be ten per cent. or less. Such selection, however, is indefensible on any ground, for every case, no matter how desperate, is entitled to the chance of renewed health which nephrectomy gives. If, taking the cases as they come, we give every patient that chance of recovery to which he is entitled, we shall find, taking the good, the bad and the very bad, that the average mortality will be large. I have operated in every renal case in which I thought that the patient had any chance of recovery—in cases in which it was clear that recovery could not take place without removal of the kidney, and in which the general condition was most unpromising. Though the mortality has been large in desperate cases, it has been small in the others. A recovery, under the deplorable conditions which prevail in advanced cases of hopeless pyonephrosis, is so gratifying that it seems justifiable to undertake nephrectomy even in the most desperate cases.

The examination of the ureter and the comparative efficiency of the two kidneys is very important, and ought to be carried out in all cases. I have never removed a kidney until I have found out that the other was there and comparatively normal. The determination of the amount of urine excreted, and its nature, is of great value; it is questionable, however, whether the method of Kelly is necessary in all cases. In many instances the diseased kidney is so blocked that all the urine excreted must come from the other kidney. With reference to routes there is some ambiguity in definitions. If we mean by the lumbar to make an incision through the back and take the kidney out between the last rib and the crest of the ilium, I am opposed to the route as unscientific and dangerous. If we mean by abdominal operation an anterior incision across the peritoneal cavity I think that is unnecessary and dangerous. I favor and practise the incision halfway between, by which we can first go into the abdomen and determine the condition of the other side; we can then make a retro-peritoneal extirpation of the kidney. By this route we enter the abdomen near the outer border of the colon; we avoid the first great danger of nephrectomy—that of taking out the only

kidney which the patient has; and we can prevent the commonest cause of death from the operation itself—hemorrhage. Finally, by this route we can determine all of the relations of the kidney, the extent and nature of the disease; in other words, we know exactly what we are doing. This is what I mean by the lumbar operation.

DR. CUSHING: I wish to congratulate Dr. Garceau on the results of these cases. I have seen something of his work and something of some of these cases; and I was very much impressed with his infinite patience, scrupulous cleanliness and minute attention to detail, all of which work together and are necessary in order to do this sort of work, and do it well as Dr. Garceau does it. It is really a little specialty within a specialty, this work on ureters, and it is very gratifying to see the developments and application of methods of precision to a department which I think many of us feel has been something of an opprobrium, and certainly something of a weariness, and often disheartening, to those who have had to take care of these long chronic cases. In regard to the first case I was somewhat sceptical as to whether it would do any good to remove the kidney in a girl where the bladder was already infected. It seemed as if the bladder would get worse or the other kidney degenerate; but the result has shown that the operation was useful and has been a great relief to her sufferings. Dr. Richardson has said precisely what I would have said in regard to the incision. The old lumbar incision in the region of the quadriceps lumborum is difficult and unsatisfactory, and a dangerous process, whereas the incision into the abdomen, not in the median line, but on the side, gives a very good field of operation, and can hardly be called a lumbar operation. The removal of the kidney by incision in the median line, however, is not particularly difficult, and has given in my hands very good results. I have had to do it several times by the median incision where the diagnosis was not well established in the beginning, and it is not particularly inconvenient, and gives a good chance to follow the ureter down as far as you want to.

In regard to the patulous urethra, as well as the urethral caruncles, which are sometimes so painful and bother the women so much, they are very easily cured by a very slight operation of removing a wedge-shaped piece from the lower part of the meatus (lower as the woman lies on her back) and bringing the edges of the wound together. I often have occasion to do it in conjunction with other operations, and it is a very slight thing to do, can be done without ether by local anesthesia, and remedies at once not only this patulous condition, which may lead to infection of the bladder, but the very distressing condition from which women suffer very much, which is commonly treated by all sorts of cauterization with little success.

DR. CODMAN: I have been a good deal interested in the subject of diagnosis of renal calculi with the x-rays, as it is a very difficult diagnosis to make, and seems to be the one thing outside of the use of the x-rays in fractures and bony displacements in the limbs in which Röntgen's discovery is likely to be of use. This diagnosis has been made with the x-ray twice in England. Vesical calculi have been reported also. I have tried six cases altogether on patients who had symptoms of renal calculi; and in none of them have I succeeded in finding a stone, although in some of them I have got fairly good photographs which show the outlines of

lumbar vertebræ and also ribs. The first case was a case of Dr. Richardson's at the Massachusetts General Hospital, where the patient had symptoms of stone and evidences of pus in the pelvis of the kidney. I photographed the patient, and there appeared a mark on the plate which was in the right place for a stone. Fortunately, before the patient was operated on Dr. Richardson suggested there might be a button on the man's clothes, and it proved there was a button on the back of the man's nightgown which showed through. Dr. Richardson operated, and found abundant pus; but there was no stone. Since then I have had five other cases, and one has come to operation and no stone was found. The difficulty is that the kidney is so far away from the plate, and standing in relation to some of the bony structures (lower ribs and spinal column), the contrast of any body in the kidney would not be brought out. The farther an object is away from the plate the more its shadow is blurred. There is another reason for the indistinctness of these photographs also. The x-rays, in passing through a thick opaque body, are more or less diffused the way ordinary light is in passing through a glass of water with an emulsion of fat in it. Hence the diffused light from all parts of a thick object blurs the sensitive plate to a certain extent, and makes the shadow of the opaque parts more ill-defined.

DR. CUMSTON: The writer of the excellent paper that we have just heard has given us the report of cases of vesical troubles due to, or kept up by, lesions of the kidney or ureter, and in which some pathological elements were found by urinalysis. We heartily agree with the reader that the catheterization of the ureters should not be practised unless some abnormal condition of the urine would lead us to suspect or suppose that there was present a lesion of one or both kidneys.

But what we desire to call the attention of this Society to are those cases of prolonged, chronic cystitis, in which nothing abnormal can be found in the urine. We have in mind three cases of this class actually under our care: one an elderly lady of some seventy-five years, and two young married women of about twenty-five or twenty-six. These patients have complained of dysuria and frequent micturition for a number of years, and their lives have been rendered unbearable by their bladders. In none was there a single abnormal element in the urine; and no lesion of the kidney or ureters could be detected. A carefully directed medical treatment was applied in two of our cases for over a year without the slightest benefit. Cystoscopic examination showed a marked hyperemia of the trigonum and fundus of the bladder. In all three the genital organs were perfectly free from any pathological condition.

In two of these patients we have recently performed vaginal cystotomy in order to keep up a constant drainage of the viscus, and much improvement is already remarked.

As to vaginal cystotomy, we prefer performing it with the thermo-cautery, because it is very rapidly executed and we think that the opening is very much less liable to contract and close up, as may happen when an incision and sutures are employed. Then again, with the thermo-cautery no sutures are needed, and thus the unfortunate result of their possible infection is not to be feared.

In the cases we have mentioned the only apparent

cause of the vesical symptoms was the extreme hyperemia of the fundus and trigonum; and we believe that this class of cases may be grouped with those of the so-called "irritable bladder" of the English writers, the pathology of which is for the present surrounded by obscurity.

DR. GARCEAU: In closing, there is one point which I wish to emphasize, and that is the ease with which an early diagnosis of suppurative disease of the kidney, whether tubercular or not, can be made. Heretofore suppurative disease of the kidney in the early stages has been suspected at most; but there has been no means of diagnosing this condition with accuracy. By using the ureteral catheters in cases in which the symptoms warrant such use, the urine can be drawn from each kidney, and the condition of each may thus be determined. The percentage of urea gives the working efficiency of the respective kidney, and is a guide to the actual work being done; while abnormal elements, such as pus, casts, etc., give valuable information as to the nature of the process going on. By resorting to this means of diagnosis an early extirpation is possible at a time when the patient's strength is not undermined by long suffering. The operation of nephrectomy need not be considered a very serious one, provided it is performed at a time when conditions are favorable for a successful issue. Before ureteral catheterization, nephrectomies were performed at a time when the kidney was thoroughly disorganized, and possibly the opposite kidney was affected; hence the large mortality. Reference is now made especially to tubercular suppuration.

Thus Newman gives a list of 33 cases of nephrectomies for tubercular disease, with 12 deaths, a mortality of 39 percent.; which is not far from the mortality from nephrectomies for other diseases of the kidney. Of these 12 cases of deaths, in six the disease was far advanced, and in two both kidneys were affected with tubercle; hence the importance of an early diagnosis.

By means of Brenner's modification of Nitze's cystoscope ureteral catheterization in the male is possible, though more difficult than in the female.

It is to be hoped that far-advanced renal suppurative disease may soon be as rare as large ovarian or fibroid tumors. Ten years ago it was not uncommon to meet with these immense tumors, whereas to-day they are only exceptionally seen in practice. This is because they are removed early.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

FOURTEENTH ANNUAL MEETING, WASHINGTON, D. C.,
MAY 4, 5 AND 6, 1897.

(Concluded from No. 4, p. 90.)

DR. FREDERIC I. KNIGHT, of Boston, read a paper on

THE CHOICE OF A SUMMER RESIDENCE IN NEW ENGLAND.

He said that there is often an opportunity for the medical attendant to be of great service to a family in indicating their summer residence, perhaps in reference to their characteristics as a family, or with special reference to an invalid or convalescent member. He has to choose between the simple air of the north country, the stimulating, rarefied air of the mountains, and the pure ozone-laden sea-air; but here again he

must choose between the island climate, the cold, stimulating air of the Beverly shore and the Maine coast, or the warm and to some enervating air of the south shore.

Dr. Knight called attention to two kinds of country places appropriate for summer residence, namely, places comparatively low in elevation, but far enough north to insure cool nights as a rule; and mountainous places which, according to their elevation, afford a dry, rarefied air very free from germs, cooler days, and often very cool nights.

We find also several kinds of sea places differing greatly one from another, and indicated for very different conditions of the system. The coast climate of New England varies greatly according to the varying exposure to the south and east winds. To be cool in summer on the New England coast one must be where the south wind blows directly from the sea. As the general direction of the line of the east coast runs nearly northeast the whole coast would have the south wind from the water if it were not for the interference of the two capes, Cape Ann and Cape Cod. North of Cape Ann as far as Hampton, N. H., where the coast line begins to turn decidedly to the east, and north of Cape Cod, especially between Cohasset and Boston, the south wind comes overland, and is a hot wind; whereas, along the eastern Maine coast, north of Hampton, N. H., and south of Cape Ann toward Boston, on what is called the North Shore, (that is, of Massachusetts Bay), including Gloucester, Manchester, Beverly, Marblehead, Swampscott and Nahant, the south wind comes from the sea. As you approach Boston from Lynn the effect of the Cape in meeting the south wind is felt, and at Boston it is a hot wind. On the south side of Cape Cod and along the southern coast of New England till it is modified by Long Island, one gets the south wind directly from the water. Everywhere north of Cape Cod the coast is exposed to the east and northeast winds, which may be very cold and raw. The shores of Buzzard's Bay are shielded from the east winds by Cape Cod, and Newport and New London receive the northeast wind modified by the same.

Dr. VINCENT Y. BOWDITCH, in discussing Dr. Knight's paper, spoke of the contrast between the enervating effect of the shore on the south side of Cape Cod and the stimulating effect of the north coast, especially the island portion of Maine. Another feature of the southern shore is the extreme moisture, whereas on the north shore articles of clothing do not readily become mouldy. Even the fogs have not the dampness characteristic of them in other localities. The light vapory mist which drives in frequently from the sea has no definite sense of moisture as it strikes the face, and in the midst of it the air frequently feels dry.

On the coast of Maine, again, the southwest wind, which in Boston has a debilitating, blustering, murky quality, is delicious in its cool, bracing and even dry quality, as it courses over the colder water of that shore. This is especially noticeable on the islands along that coast, and the climate generally has more of the typical equability of island climates. The snows in winter are not so deep and do not last so long as on the mainland. In the vicinity of Mt. Desert doubtless the presence of the mountains there has an effect upon the quality of the atmosphere and would partly account for what is often spoken of, the

effect of sea and mountain air combined. Its peculiar dryness, even though on the coast, has been so marked often that I have frequently thought that certain phthisical patients who need a very bracing atmosphere might improve there, although I have never quite dared to recommend it for such cases.

Dr. SAMUEL A. FISK, of Denver, read a paper on

DIGESTION VS. DRUGS IN THE TREATMENT OF PULMONARY TUBERCULOSIS.

In the course of his paper he said: The bacillus has assumed such monstrous proportions in our eyes, that he must be hunted and killed at any cost. It has been remarked that more patients have been killed with antipyrin than have died of *la grippe*—whatever that may be. I sometimes wonder whether the same thing could not be said of creosote and tuberculosis. My own experience has not been favorable to the use of creosote. I have seen it upset the digestion more often than accomplish anything else; and the best thing that I can say for it, is that it has the endorsement of a member of this Association, for whose opinion, based upon a large experience, I have great deference. In a large number of cases that I see, one of the first things that I have to do is to stop the creosote, and give calomel and potash.

In my opinion, no drug should be administered which interferes with the digestion, with the proper nourishment.

He quoted Dr. Trudeau, who writes in a recent article: "At the Sanitarium, the utmost attention is given to the alimentation of the patient and every attempt is made to induce him to take and digest as much nourishing food as possible. . . Little stress is laid on the administration of drugs, except when necessary to relieve symptoms; but cod-liver oil, the hypophosphites and arsenic are very generally made use of."

Dr. RICHARD COLE NEWTON, of Montclair, N. J., presented

SOME PERSONAL OBSERVATIONS UPON THE EFFECTS OF CHANGES OF CLIMATE UPON MEN AND ANIMALS.

His conclusions were as follows:

(1) That the change of climate from the Rocky Mountains to the sea-board is more severe and dangerous than the reverse, especially to young children and horses.

(2) That a medium, or even high, altitude is more beneficial than otherwise to nervous diseases and the diseases of women, as well as to phthisis, and is not unfavorable to rheumatism.

(3) That in the climate of Northern Texas and New Mexico, nephritis in all forms is exceedingly rare, while aneurism is somewhat common in the latter territory.

(4) Wounds do remarkable well in all the parts of the Southwest in which I served, even in Fort Sill, which is unhealthy by reason of malaria.

(5) That the ideally healthy and satisfactory life is a nomadic one.

(6) Let us remember that "*Cælum non animum mutant qui trans mare eurrunt*" (Change of climate does not bring change of disposition), nor, for that matter, of predisposition. Precious and even invaluable as change of climate often is, in a number of diseased conditions, it is not always what is most needed.

Let us more often be content with smaller doses of climate, and supplement them with larger doses of hygiene, both moral and physical.

As to his observation of diseases among the Indians, Dr. Newton said he saw but little. They seemed, in the Indian Territory, quite susceptible to malaria, had learned to beg for quinine, which they took greedily. Those who could talk a little English would hold out the hand and ask for "white powder." If a small amount was poured into the palm, the applicant would say, "Heap, heap."

While campaigning, or "scouting," as it is generally termed, with Indian scouts, he had heard them coughing all night long, and was told by the officer in command that they were very subject to colds, especially after they had taken a sweat bath. Once in a while, probably every two or three months, the New Mexican Indian builds a little oven or tent of withes, and covers it with skins, until it is nearly air-tight. He then heats a number of stones, lays them upon the floor of the little oven and covers them with a blanket. He will then crawl in and lie and sweat for two or three hours, after which he will run and plunge, naked, into an ice-cold stream. This procedure often results in severe colds.

DR. J. B. WALKER, of Philadelphia, read a paper on

OIL OF TURPENTINE AS A REMEDIAL AGENT.

He dwelt especially upon its effects in catarrhal affections and as a hemostatic where the lesion was in the mucous membrane. In gastric ulcer, whether for its influence on the ulcerative process or as a hemostatic, it ranks, *par excellence*, both for efficiency and acceptability by an irritable stomach. Given in small doses, two to ten drops in water, sweetened by the oleosaccharatum anisi, each dose prepared as taken, its acrimony is avoided, and the most sensitive stomach will retain it. In catarrhs, sub-acute or chronic, whether in stomach, bowels, or bronchial tubes or urinary tract, as a stimulant, attractive, reaching every mucous membrane of the body either in its ingestion or elimination, its virtues are invaluable, modifying secretion and influencing cell nutrition. In the winter coughs of the aged and infirm, its general stimulant action is an additional advantage to its local effect.

DR. R. C. NEWTON called attention to the value of turpentine as an application to wounds and also in nose-bleed.

DR. L. D. JUDD, of Philadelphia, related the histories of

TWO REMARKABLE RECOVERIES FROM MALIGNANT DIPHTHERIA.

Calomel was used in heroic doses in both. In one of the cases, an adult woman, he gave twenty grains at the first dose and ten grains every hour for thirty-five hours when a copious dejection occurred; smaller ones had preceded, but not until 365 grains had been given did we get the characteristic action; then the calomel was stopped. She ejected from nose and mouth at intervals during the exhibition of the drug large pieces of membrane, although no gargle or spray was used. We had little hope of saving this woman up to the time she had taken fifteen doses, or 160 grains; but from that time on she steadily improved in strength and appearance.

About every three hours a mild solution of chlorate

of potash was given during the treatment. Calomel was dusted over the initial lesion on the finger, which took on a healthy action. She made a splendid recovery, was only inconvenienced for a short time from the partial paralysis of the muscles of deglutition and impairment of the sense of touch in hands and feet. These symptoms rapidly disappeared under the use of faradization; there was not the slightest evidence of ptyalism or other mal-effect. The remarkable specific action of calomel in large doses was here magnificently exemplified.

DR. JOHN WINTERS BRANNAN, of New York, said he was inclined to try Dr. Judd's method of treatment at the first opportunity. During the past four years he had seen some two or three thousand cases in the Willard Parker Hospital in New York, and his experience with calomel differed in some respects from that of Dr. Judd. In the first place, Dr. Judd stated that he had found calomel an aid in the diagnosis of diphtheria because of the slowness with which it produces catharsis in that disease. In the Willard Parker Hospital, it is the routine practice to give each patient small doses of calomel, repeated every hour or two, until the bowels are well opened. The results of this treatment are all that can be desired, and they are never obliged to resort to other laxatives.

In the second place, Dr. Judd said that he had never seen any hurtful or depressing effects from the large amounts of calomel he is accustomed to give. Here, again, Dr. Brannan's experience conflicts with his. It was the custom at one time in the hospital, previous to the introduction of antitoxin, to employ calomel sublimates for the relief of laryngeal stenosis. The stenosis was often apparently relieved, but it was noted that the patients were afterwards markedly anemic. In fact, in passing through the convalescent wards, it was possible to pick out by their pallor those patients that had been subjected to fumigation. It is true that the calomel was not administered in the manner followed by Dr. Judd, but in both cases the specific effect of the drug was sought and obtained, and Dr. Brannan thought that the harmful results would also be the same.

DR. C. C. RANSOM, of New York, read a paper on the

TREATMENT OF GOUT BY NATURAL MINERAL WATERS.

He outlined the many things to be considered in the selection of a watering-place for gouty patients. As a rule, such patients are nervous and irritable, and need a pleasant environment where they can be occupied and diverted and lead an out-of-door life, while their treatment is made a pleasure rather than a drudgery. The fact must also be borne in mind that results of treatment may be obtained from the hydrotherapeutic standpoint alone, irrespective of the mineral ingredients contained in the water used. The analysis of the water is, therefore, not alone sufficient in the selection of such a place, for unless the facilities for administering the waters are adequate, and the details of the bathing procedure are carefully carried out, the treatment, instead of doing good, may be productive of serious ills. While Dr. Ransom believes thoroughly in the internal administration of mineral waters, he holds that the most valuable mineral waters in the treatment of this disease are those that are used externally in the form of baths.

It is hardly conceivable that the chemical ingredi-

ents of most natural mineral waters are held in them in sufficient quantity to produce *per se* any marked curative effects upon the economy when taken internally. This is especially true of the alkaline mineral waters, the principle of whose action is to render alkaline the blood and the secretions. While not altogether decrying the use of alkaline waters, believing that they have some value in augmenting the secretions and stimulating functional activity, yet he does not believe that they alone should be depended upon to effect a cure, but should only be used as an adjunct to the bath treatment.

Dr. Ransom's experience with the mineral baths has been especially in the use of the waters of Richfield Springs, which are sulphur waters. He says: I naturally feel that this class of waters is unsurpassed in the treatment of the gouty diathesis, and I may be justified in my opinion by the most excellent results which I have obtained from their use — results which, so far as I can learn, have not been surpassed at any springs.

DR. J. N. DANFORTH, of Chicago, presented a paper on

RENAL DISEASES AS AFFECTED BY CLIMATE.

He said: Speaking from my own personal experience and observation in the field of renal pathology, and especially with reference to the parenchymatous and interstitial nephritis, I am convinced that the former is not infrequently a product of malarial poisoning. I have seen cases repeatedly which I felt constrained to attribute to repeated or habitual exposures to malarial effluvia, and which I could attribute to no other cause. Many of these cases gave distinct histories of repeated malarial outbreaks of a tertian or quartan type, and admitted repeated visits to localities reeking with paludal poison.

In one case I found the plasmodia of A. Laveran, together with a well-marked malarial "cachexia," decided albuminuria, hyaline and epithelial tube-casts, and edema of the feet. All these symptoms disappeared under the use of quinine (18 grains given every forenoon in three equal doses), and the patient remains well at this time, six months having elapsed. It is not impossible that many of the cases loosely attributed to the "cold and wet" may really be due to malaria. A question of great interest is how tubal nephritis is produced by malaria. A very rational explanation is that it is due to the irritant effect of the plasmodia themselves upon the renal tubules or their epithelia. But this is conjectural, as I have never had the opportunity of examining a kidney in a case of malarial nephritis.

I have not been able to collect any trustworthy evidence as to the causation of interstitial nephritis by climatic changes, although I have sought diligently for such evidence.

The curative effect of a uniformly warm, dry climate, which is free from paludal poisoning, is unquestionable. I have seen the beneficial results of a residence in Algiers, the south of France, Northern Italy, Barbadoes, and the Indian Peninsula time and again. Our own Southern States are equally beneficial in localities where the moisture is not too great, but thousands of acres of virgin soil must be subdued by cultivation, and thousands of other acres of cypress swamps must be drained before patients can be sent to our South without a careful discrimination as to time and locality. The South of Europe has been sub-

jected to hundreds of years of close and severe cultivation, so that the sources of malarial poisoning are few and far between. Our "Sunny South" needs just that treatment to render it a salubrious and curative climate for Bright's disease, except in favored localities, which have already passed through the early stages of civilization and cultivation.

DR. D. R. BROWER, of Chicago, in a paper on

CLIMATE IN RELATION TO THE NERVOUS SYSTEM,

considered, among other diseases, insanity. While some cases are very much improved by proper climatic conditions, there is some difficulty in selecting a climate for this complex condition of the nervous system, even greater than for cases of tuberculosis. As a better knowledge of insanity is being diffused throughout the profession, a greater number of cases will be treated in private houses, in the homes of physicians and in ordinary hospitals, and this will give a better opportunity to obtain the modifying influences of climate in the disorders of nutrition that have developed this special form of nervous disease. There has been in times past too great a tendency on the part of the family physician to hurry off a case of insanity to the nearest and most readily accessible insane hospital, without properly considering the relations that climate may bear to this grave disorder. In the simple form of melancholia a moderately high altitude inland, because of its stimulating and tonic properties, is of service, especially in those cases that have originated in low-level and marine climates. In the treatment of this form of insanity, as in the treatment of insanity generally, Dr. Brower often moves patients from one institution or hospital to another, if the improvement has not been satisfactory or if it has not commenced; occasionally a stationary case is urged on to improvement and to recovery by a change in locality where the equipment of the institution may not have been even as good as the one from which the case has been removed. Slight modifying conditions are sometimes sufficient to turn the tide in this subtle affection from or toward recovery.

It is unfortunate that there are so few private hospitals for the insane located in moderately high-level climates. In the incipency of these cases of mental depression there is some advantage in travel with a well-selected companion in the climates indicated, such as the White Mountains, Adirondack Mountains, the mountains of Virginia and of North Carolina. In the mountains of North Carolina the conditions are favorable not only for the summer, but for winter residence in the neighborhood of Asheville and Linville. The latter is especially a very desirable locality. The Ozark Mountains and the lower levels in the Rocky Mountains also well represent the stimulating and tonic properties of elevation. The patient may be moved with advantage from one place to another, securing thereby mental diversion and a possible relief from the constant tendency to introspection. In the agitative form of melancholia, as well as in cases of mental exaltation, better results will be had in a low-level or marine climate. The sedative and soporific effects of a lower-level or marine climate are indicated in these cases, and the coasts of Southern California, New Jersey, Long Island, Massachusetts and Maine offer many localities specially well suited to this form of insanity; fortunately, in most of these several localities there will be found

excellent private institutions for the care and treatment of insanity. The milder cases of these forms of mental disturbance may be treated successfully in these several localities with the aid of a competent nurse or a travelling companion.

At the business meeting it was

Resolved, that the Association learns with much regret that the Weather Bureau has been obliged to discontinue the publication of, and the work exemplified in its recent publication, "Climate and Health."

Resolved, that this Association would urge upon the Secretary of Agriculture and the Chief of the Weather Bureau the desirability of resuming the said publication, and that the members of the Association urge upon the members of Congress from their States to furnish an appropriation for the purpose.

Dr. Hermann Weber and Dr. Charles Theodore Williams of London, were elected honorary members.

The following officers were elected: President, Dr. E. O. Otis, of Boston; Vice Presidents, Dr. Beverley Robinson, of New York and Dr. C. F. McGahan, of Aiken, S. C.; Secretary and Treasurer, Dr. Guy Hinsdale, of Philadelphia.

Bethlehem, N. Y., was selected as the next place of meeting.

Recent Literature.

Abdominal Surgery. By J. GREIG SMITH, M.A., F.R.S.E., Surgeon to the Bristol Royal Infirmary, Professor of Surgery, University College, Bristol. Fifth edition. Vols I and II. London: J. & A. Churchill. 1896.

This fifth edition of J. Greig Smith's "Abdominal Surgery" may almost be considered a new work. Some of the sections have been re-written; many have new matter introduced. There are several articles on new subjects; for example, "The Surgery of the Abdominal Parieties," "Symphysectomy," "Subphrenic Abscess," and "Surgery of the Ureters." The previous editions of the book have become so well known that it is only necessary to say that the high standard established by the author in his first edition has been maintained, and all possible improvements have been introduced. This work is to-day one of the standard works on abdominal surgery. The large experience of Mr. J. Greig Smith has enabled him to give to the work an individuality that is sadly missed in the majority of books. A thoroughly judicial spirit, a clearness of description and an attention to detail combine to make the work invaluable to the operating surgeon.

The Principles of Bacteriology. A Practical Manual for Students and Physicians. By A. C. ABBOTT, M.D. Third edition. Philadelphia: Lea Brothers & Co. 1895.

The popularity of this book is attested by the appearance of a third edition. It has been considerably improved by the revision of some chapters and the insertion of new drawings.

The book may be heartily recommended, both to those who have use for clear directions concerning laboratory manipulations as well as to those who wish to gain some knowledge of the chief facts of bacteriology by reading.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JULY 29, 1897.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE NEW TUBERCULIN.

THE first reports of cases treated with Koch's new tuberculin (tuberculin T. R.) are not altogether encouraging.¹ Professor Schultz, of Bonn, reports on nine cases treated according to the rules laid down by Koch in his paper of April 1, 1897. In several instances the general unpleasant symptoms which followed the use of the old tuberculin were observed. In one patient laryngeal lesions developed during the treatment, and the general condition was such that it was deemed best to give up the injections. Another patient, who had been gaining previously to the administration of the tuberculin, developed intestinal symptoms, lost flesh, and wished no further treatment. Four patients went through the course of treatment unchanged in general condition. One, having dry pleurisy, improved both locally and in general condition. The remaining two were out-patients, and improved during the treatment. Professor Schlutz thinks that it would be impossible to ascribe either the improvements or the ill effects to the action of the tuberculin T. R. Time alone will show the course of the disease in the patients who have gone through the "cure."

The report from Prof. B. Fränkel's clinic at the Charité Hospital comprises 19 cases, 15 of whom had completed the course of treatment. Of the total number of cases four were cases of lupus. Only four of all the patients were found who were able to receive the treatment according to the suggestion of Koch, that is, doubling the doses of tuberculin each time the injections were given. Of the symptoms which developed in the remaining patients the fever was the most serious. There seemed to be great variation in the material furnished as regards the symptoms produced; for example, using some freshly obtained material upon six patients who had previously shown no ill effects from the injection, a whole cubic centi-

¹ Deutsche Med. Woch., No. 28, July 8, 1897.

metre of the original fluid, five out of the six reacted with severe chills and fever from 104° to 106° F. Another patient, who had completed the treatment and had not reacted either to 40 mg. of the tuberculin T. R. or to 150 mg. of the old tuberculin, reacted fourteen days later to new material, with chills and fever.

Pulse and respiration increased proportionally with the fever in all cases. Other unpleasant symptoms complained of during the treatment were headache, dulness, pains in the limbs and palpitation of the heart. No enlargement of the spleen was observed and no changes of account were observed in the number of leucocytes. The weight of the 15 patients who had completed the course of treatment varied as follows: Seven increased in weight, two remained unchanged and five lost weight, in two cases 10 pounds. Urticaria or herpes were not observed. There was no abscess developed during the treatment though some reddening or infiltration of the skin and occasional swelling of the neighboring glands was observed.

No complaint was made by either of the writers that the tuberculin was not sterile, as has been the case in some of the material furnished by Italian and American experimenters.

The most which can be made out from these incomplete reports is that with the tuberculin T. R., as furnished by the manufacturers, results cannot be obtained to correspond with the results to be expected from reading Koch's article. And this is exactly what every-one would be led to expect, for the difficulties in the way of carrying out Koch's process are manifestly so great that the slightest error or carelessness is bound to give the unpleasant results of the old tuberculin reactions. That there will come something of value from this discovery is certainly to be desired; but it seems as though a better-known and more stable compound must be determined before the material can be utilized by the general practitioner.

A RESEARCH LABORATORY FOR INDIA.

ONE of the advantages which the world at large has derived from the extension of the British Empire has been the more comprehensive study of disease in forms not ordinarily met with at home. India and the Eastern possessions in general have afforded a most valuable and prolific field for scientific research in the etiology of diseases peculiar to those races and climates. The difficulties in the way of establishing adequate centres of research have been manifold, but progress has been constant and practically uninterrupted.

A plan is now on foot and has, in fact, been agitated for some time past, to establish one or more bacteriological institutes in the East for the special investigation of Indian diseases.

In reply to the suggestion that such an institute be established in commemoration of Victoria's long reign, the following paragraph in the *British Medical Journal*, and quoted as sent through the Foreign office, occurs:

Your proposal seems well calculated to attain those ends (namely, the investigation of Indian diseases), and there could be no more fitting commemoration of Her Majesty's long and beneficent reign. Every year there is an appalling mortality from malarial fever and from cholera, typhoid fever and other zymotic diseases. Snakebite and rabies also add to the annual death-roll. During the present year there has been a visitation of bubonic plague which, in addition to destroying many thousand lives, gravely imperilled the foreign commerce of India, on which the prosperity of the country so largely depends. The best hope of combating these diseases which are the cause of much suffering and loss of life, appears to lie in the development of bacteriological and cognate researches under scientific medical guidance, and carried on with due regard to medical requirements and the interests of humanity.

It is to be hoped that any political difficulties that may stand in the way of such a project may be successfully met, and that after the establishment of the institutes sufficient funds may be forthcoming to prosecute continuously the work undertaken. In that case, there can be no doubt that many matters of much scientific importance would meet the careful study they demand.

THE BACILLUS ICTEROIDES.

THE Legislature of Uruguay has bestowed upon Prof. Giuseppe Sanarelli, Director of the Institute of Experimental Hygiene of the University of Montevideo, the discoverer of the bacillus icteroides, the latest specific micro-organism of yellow fever, the honorary citizenship of Uruguay and a donation of ten thousand pesos in recognition of his distinguished contribution to science. At the same time the legislature records its regret that "the unhappy condition of the country does not admit of its doing more to evince its gratitude to a physician and nature-student who has already laid those regions under so many obligations."

Heat, moisture, darkness, want of ventilation, are favorable to the preservation of the bacillus of icteroides, as they are to that of most micro-organisms, but the common moulds of the atmosphere constitute the great protectors of this bacillus and explain its development and tenacity of life on board of certain vessels. Sanarelli has experimented with six species of moulds isolated at haphazard from the atmosphere of his laboratory; and all of these showed themselves capable, though in different degrees, of favoring the revivification and multiplication of his bacillus. He suggests the possibility of the existence, especially in localities where yellow fever is prevalent, of some mould hitherto unknown and endowed with truly specific and much greater favoring power.

He entertains a "well-founded" faith that it will soon be possible to apply to man a specific preventive and curative treatment of yellow fever. What he has done is of much interest. We most earnestly hope that his conclusions may be confirmed, and that his expectations of practical results to humanity will be speedily realized.

There are, of course, some of our fellow-citizens who will be greatly shocked that dogs and horses should have been inconvenienced in the course of these investigations; but even this may perhaps be forgiven

should a means result with which to check or to prevent a repetition of those outbreaks of yellow fever by which certain cities have in the past been devastated.

MEDICAL NOTES.

A JOHNS HOPKINS UNIVERSITY APPOINTMENT.—The trustees of the Johns Hopkins University have appointed Dr. John M. T. Finney to be associate professor of surgery.

APPOINTMENT.—The College of Physicians and Surgeons, Chicago—the Medical Department of the University of Illinois—has chosen A. H. Burr, M.D., adjunct professor of practice of medicine.

DR. C. THEODORE WILLIAMS has been requested to represent the University of Oxford at the International Medical Congress which will commence at Moscow on August 19th, and has accepted the nomination.

THE HULL BIOLOGICAL LABORATORIES.—The Hull Biological Laboratories of the University of Chicago were formally dedicated on the 2d inst. The address was made by Professor William H. Welch of Johns Hopkins University. The subject was "Biology and Medicine."

THE EFFECT OF CIVIL-SERVICE EXAMINATIONS.—It is stated that eighteen women who were recently examined under Governor Black's new civil-service scheme have suffered from nervous prostration as a result of the excitement attending the examination. The examinations were conducted on the question of the applicants' "fitness" for the positions they sought to occupy. If such is to be the general result of the new system, there can be no question that the scheme must be regarded a failure. It is, to say the least, unfortunate, that any new source of nervous break-down, which is not absolutely necessary, should be forced upon our public servants.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, July 28, 1897, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 25, scarlet fever 14, measles 16, typhoid fever 8.

AN ACT TO PROHIBIT THE USE OF POISONOUS SUBSTANCES IN THE PRACTICE OF DENTISTRY.—The next General Court of Massachusetts may be asked to pass the following bill:

SECTION 1. The use of any of the amalgams of mercury as a filling for dental cavities, or the use of red or pink rubber plates which contain mercury or any of its compounds, is hereby prohibited.

SECT. 2. Any dentist who shall violate the provisions of this act shall be punished by a fine of not less than fifty nor more than one hundred dollars, or by confinement for a period of three months in the county jail, or both, for each and every offence.

NEW YORK.

A PHENOMENAL APPETITE.—The following newspaper despatch from Burlington, N. J., July 17th,

would seem to break the record: "For some time past the appetite of Peter Cunningham, an employee of Shedaker's farm, had been enormous. He ate more than all the rest of the hired men and family, and his hunger could not be appeased. On Monday Dr. Stowell was summoned. He went to work, and yesterday, according to Cunningham and the doctor, the former was relieved of fifty-one small frogs and a worm forty-five feet in length. Both Cunningham and the doctor say they have made no mistake in the number of frogs and the size of the worm."

DEATH OF DR. WILLIAM M. THURMAN.—Dr. William M. Thurman, a well-known practitioner of New York, died at his residence in that city on July 21st. He was a graduate of the College of Physicians and Surgeons, New York, in 1864. Dr. Thurman was for many years identified with the St. John's Guild, and was among the organizers of its Floating Hospital and Seaside Hospital projects.

MIDSUMMER MORTALITY IN NEW YORK.—The midsummer mortality in the city is not at all excessive this season. During the week ending July 24th there were reported 920 deaths, a falling off of over 50 from the preceding week. There was no death from sunstroke, while in the week previous there were 14 from this cause. There was one death from small-pox, as in the week ending July 17th. There were 51 deaths from pneumonia against 35 in the previous week, the smallest mortality from this disease for about two years. The mortality among infants is naturally large at this period of the year, and of the 920 deaths, 516 were in children under five years of age.

Miscellany.

THE BICYCLE AGAIN.

THERE is still doubt in some quarters of the value of the bicycle as a means of promoting health. The *New York Medical Record* for July 17th discusses the matter editorially, apropos of an article on "The Hidden Dangers of Cycling," by Dr. Shadwell, who has previously written on the same subject. His view is a gloomy one, and would tend to consign the bicycle once and for all to disuse, at least so far as women riders are concerned.

No doubt a difference of opinion on the subject is still and always will be justified; but it will require many more statistics than are yet available to persuade either the medical or the general public that the disadvantages of wheeling outweigh its manifold and evident advantages. Individual cases must certainly be judged on their merits; and common-sense here, as in all other matters, must determine the point beyond which riding ceases to be an advantage. That its value is decided in many cases, no one with experience will now deny; that it is an abused form of exercise among some of its devotees every one is willing to admit; but no further generalization seems at present possible.

The writer in the *Medical Record* makes the dogmatic statement that "Any valvular disease should be an absolute bar to cycling, as the heart is the organ

principally exercised." This is undoubtedly a very safe position to take. At the same time it is rather amusing to turn to another journal, the *Deutsche Medicinische Wochenschrift*, and find that Dr. Siegfried, of Berlin-Bad Nauheim, reports a number of cases where the bicycle was used as the method of cure: in one patient we find the statement "arterio-sclerosis, marked arrhythmia cordis"; and in another, "cardiac insufficiency." Of course, Dr. Siegfried makes his patients understand that it is "eurygymnastik, aber keinen sport." We ourselves know of a physician who is blessed with a double aortic murmur, and yet does the travelling necessary to a large practice on his wheel and has done so for several years past.

The *Record* sums up the matter well in the following paragraph:

The fact that there are dangers connected with cycling cannot be denied; these, however, are not hidden ones, but are more or less palpable to every observer. It may be said that there is danger in teaching the practice to the quite young. Properly, cycling should not be carried on to any extent while the body is undergoing development. Any valvular disease should be an absolute bar to cycling, as the heart is the organ principally exercised. Acute inflammation of the genital organs should forbid the use of the machine to women, although the exercise is often beneficial in chronic cases of uterine disease. The question finally resolves itself into one of moderation or excess, and the personal equation in this respect is variable. A healthy man may be able to do one hundred or one hundred and fifty miles without exerting himself; while another, to all appearances equally healthy, should not do more than forty or fifty. Cyclists are too apt to be carried away by the spirit of emulation, and when they do so with riders of a superior capacity they must expect to suffer. Each cyclist should be a judge of his or her own capacity.

In any case it is certain that, for good or ill, the bicycle has come to stay.

AN EFFORT TO CORRECT MEDICAL CHARITY ABUSES.

THE *Journal of the American Medical Association* prints the following:

"The medical profession in New York City has determined to make a united effort to correct the medical charity abuses, and for that purpose a joint committee composed of two representatives of each of the following societies have met and organized, namely, the New York County Medical Association, the New York County Medical Society, the New York Medical League and the Society for the Advancement of Medical Practice. The committee will sit through the summer, prepare plans and data, appeal to all the medical societies of the State for sympathy and aid, and have ready for presentation to the Legislature when it convenes next winter a bill meeting with the approval of the entire medical profession. We are pleased to see such harmony exist, and believe that by the united efforts of the various medical bodies throughout the State, the crying abuses can and must be corrected. The bill offered last year obtained the unanimous support of Senate and Assembly and only failed of becoming a law by the neglect of the Executive giving it sanction. Our best wishes are for the success of our brothers in New York, and we are sure that the whole profession in the republic gives them its moral support."

Correspondence.

THE PEOPLE OF THE STATE OF COLORADO ON RELATION OF FRANK JEROME vs. THE REGENTS OF THE UNIVERSITY OF COLORADO.

DENVER, COL., July 17, 1897.

MR. EDITOR:—This case, decided by the Supreme Court of the State of Colorado in an opinion written by Mr. Justice Campbell, and filed June 1, 1897, involves points of such interest to the medical profession, that I take the liberty of rehearsing some of the principal points and so calling it to the attention of the profession in a way that I have not seen done as yet.

The main issue was as to whether the Regents of the University of Colorado had a right to conduct the last two years of the medical course at Denver. To set forth the condition and the facts somewhat briefly, the University of Colorado was created by an Act of the Territorial Legislature, approved November 7, 1861. Article 2, Section 1, of said Act declares that "an institution of learning is hereby created, authorized, established and instituted at the City of Boulder, in the territory of Colorado." Section 12 of this same Act further declares that "said University shall be located at the City of Boulder." When Colorado was admitted as a State, and the work of education was being carried on by the trustees in the exercise of the authority conferred by the said Act, and while these provisions of the law were in full force, this institution was expressly adopted and declared to be a State institution and its location was specifically confirmed. Later on, the Supreme Court of the State (9th Colorado, page 626), held that the "location of the agricultural college and certain other institutions having been fixed by the Constitution, such locations cannot be changed except by the Amendment of the Constitution." A further section of the Act (Section 12, Article 9, of the Constitution) creates the office of the Regents of the University (Section 4,593) and provides that "the Board of Regents shall have the general supervision of the University, and the exclusive control and direction of all funds and appropriations for the University." Section 4,395 provides that "the University shall include a clinical, philosophical, normal, scientific, law and such other departments, with such course of instruction and elective studies, as the Board of Regents may determine, and a department of the physical sciences, and the Board shall have authority to confer such degrees and grant such diplomas and other marks of distinction as are usually conferred and granted by other Universities; and the Board of Regents is authorized and required to establish a preparatory department, which shall be under the control of said Board of Regents, as are the other departments of the University."

The italics are mine, and are intended to call attention to the fact that the Regents were only required to establish a preparatory department, and that there was no compulsion making it necessary for them to establish a medical department.

On the 5th of May, 1883, "it was agreed to establish and organize a Medical Department to the State University," and in pursuance of this resolution, the Medical Department opened for work in the fall of 1893, all of the instruction being given on the University grounds. All instruction was given there until 1892, when the Regents voted unanimously "that the Medical Faculty may conduct their lectures in Denver for said two years," (that is, the last two years of the three years' course), with the understanding "that the appropriation heretofore granted to the Medical Department shall not on that account be increased, and this resolution is with the further understanding that all graduating exercises shall be held at the University proper, and that the instruction for the first year of the course shall be given at the University; that this resolution shall remain in force until satisfactory clinical advantages can be had at the University." To

this end a building was rented, a free dispensary opened, and lectures given, by the Medical Department of the University of Colorado at Denver: the graduating exercises being held, degrees conferred, business office kept and the entire first-year course conducted at Boulder.

At this time there were already two medical schools in existence in Denver, depending on their tuition fees for their support, so that the coming of the State school, backed by the State's finances, and offering tuition free, or at a nominal fee, meant extinction or, at the best, a serious crippling. At this point the Attorney-General (Populist) of the State was appealed to; and he gave it as his opinion that there was no violation of the law in the conduct of the Regents of the State University. Then the District-Attorney for the County of Arapahoe was appealed to, and he refused to bring action. Then Mr. Frank Jerome, a citizen of the State of ten years' standing, and a resident of and a free-holder and tax-payer in the City of Denver, brought suit. The case was argued before the Judge of the District Court, and decided in favor of the Regents of the State University on the broad ground of expediency. The case was then carried to the Supreme Court, and it was advanced on the docket on the grounds that "the determination of a constitutional question is necessary to the decision of the controversy." It was contended by the Regents that Mr. Jerome had no right to bring suit, to which the Court replied that as the District Court "permitted the relator to file his complaint, at least, we must assume that such permission was given from its conduct of the case. No objection was made by the defendant in any form, either by motion, demurrer or answer, to the right of the relator either to bring or prosecute the proceeding." And it furthermore said, "unless, therefore, the proceeding may be maintained by a private party, it will be readily seen that there might be a miscarriage of justice, for if the Attorney-General, with the inconsistent duties imposed upon him by law, of representing both parties to the controversy, should conclude to act in the double capacity, or for any reason concede that the Regents should not be disturbed, there would be no practical way of correcting the wrong, however flagrant might be the conduct of which the Regents were guilty." As regards the principal question, the Court said "we do not find much difficulty in its determination," and further said "that the conducting of the last two years of the course in Denver is practically a removal of the Medical Department from Boulder scarcely admits of a reasonable doubt," and said still further "to run the school at Boulder, while the real work of the University in any of its integral parts is done elsewhere, could be an evasion of the letter and spirit of the statutes of the Constitution." It went on still further to say that the supervision of the Regents "must relate to, and be confined to the University, and all its departments, as located at Boulder and not elsewhere." The judgment of the District Court was reversed, and the "cause remanded, with instructions to grant the right prayed for by the relator excluding the defendant corporation from exercising the franchise of teaching medicine at Denver."

In accordance with this decision, the Regents are obliged to conduct their Medical Department, if they conduct one at all, at the City of Boulder. It is claimed that they are precluded from doing this properly, on the ground that Boulder does not offer sufficient clinical material. It will be seen that in 1850, when the Medical Department of the University of Michigan was established at Ann Arbor, the size of that city was 4,868, and of the State 397,654, and yet they had 95 students in medicine; and that in 1890, shortly before the second and third years of the medical course of the University of Colorado were moved to Denver, the population of Boulder was 3,300, and that of Colorado 412,198 (the conditions being about the same as existed at Ann Arbor in 1850); and that in 1890 the population of Ann Arbor was only 9,431, while the University had 375 students in medicine.

Very truly yours,

SAMUEL A. FISK, M.D.

METEOROLOGICAL RECORD

For the week ending July 17th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 4,221: under five years of age 2,196; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping-cough, erysipelas, and fever) 1,370, diarrheal diseases 1,130, consumption 339, acute lung diseases 184, diphtheria and croup 85, typhoid fever 42, whooping-cough 41, scarlet fever 26, measles 20, cerebro-spinal meningitis 20, erysipelas 5, small-pox 1.

From whooping-cough New York 8, Washington 7, Chicago 5, Philadelphia 3, Brooklyn and Cincinnati 4 each, St. Louis and Pittsburg 3 each, Boston, Cambridge and Woburn 1 each. From scarlet fever New York 11, Philadelphia 4, Boston, Haverhill and Taunton 2 each, Chicago, Brooklyn, Baltimore, New Bedford and Somerville 1 each. From measles New York 10, Brooklyn

4, Chicago 2, Cincinnati, Pittsburg, Providence and Fall River 1 each. From cerebro-spinal meningitis New York 9, Boston 5, Baltimore, Lowell, Somerville, Malden, Quincy and Everett 1 each. From erysipelas Philadelphia and Boston 2 each, New York 1. From small-pox New York 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,392,524, for the week ending July 10th, the death-rate was 15.1. Deaths reported 3,192; acute diseases of the respiratory organs (London) 116, diarrhea 170, measles 143, whooping-cough 75, diphtheria 59, scarlet fever 33, fever 24.

The death-rates ranged from 7.3 in Croydon to 23.1 in Preston; Birmingham 16.4, Bolton 14.6, Bradford 15.8, Hull 15.3, Leeds 11.8, Leicester 11.3, Liverpool 20.0, London 15.1, Manchester 18.7, Newcastle-on-Tyne 14.9, Portsmouth 12.9, Sheffield 15.3, Sunderland 14.7.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 17, 1897, TO JULY 23, 1897.

Leave of absence for two months and ten days, to take effect upon being relieved from temporary duty at the Soldiers' Home near Washington, D. C., is granted CAPTAIN CHARLES M. GANDY, assistant surgeon, who will, upon the expiration of leave of absence, report for duty at Fort Mason, Cal.

CAPTAIN GEORGE MCCREERY, assistant surgeon, is relieved from duty as attending surgeon and examiner of recruits at Boston, Mass., and ordered to report for temporary duty at the Soldiers' Home near Washington, D. C., relieving CAPTAIN CHARLES M. GANDY, assistant surgeon.

So much of the order as directs FIRST-LIEUT. HENRY R. STILES, assistant surgeon, to report for duty, is amended, so as to direct him to report for duty at Fort Preble, Me., relieving CAPTAIN HENRY S. T. HARRIS, assistant surgeon.

The extension of leave of absence granted CAPTAIN ROBERT R. BALL, assistant surgeon, Fort Adams, R. I., is extended until October 15, 1897.

So much of paragraph 16, S. O. 162, A. G. O., July 16, 1897, as relates to the officers hereinafter named, is amended to read as follows:

CAPTAIN FRANK R. KEEFER, assistant surgeon, is relieved from duty at Washington Barracks, D. C., to take effect upon expiration of his present leave, and ordered to Fort Walla Walla, Wash., for duty.

CAPTAIN WILLIAM D. CROSEY, assistant surgeon, upon being relieved from duty at Fort Missoula, Mon., is ordered to Fort Sam Houston, Tex., for duty.

FIRST-LIEUT. ALEXANDER H. STARK, assistant surgeon, upon arrival of CAPTAIN CROSEY at Fort Sam Houston, Tex., is ordered to Washington Barracks, D. C., for duty.

CAPTAIN HENRY S. T. HARRIS, assistant surgeon, upon being relieved from duty at Fort Preble, Me., by FIRST-LIEUT. HENRY R. STILES, assistant surgeon, is ordered to Fort Washakie, Wyo., for duty, relieving CAPTAIN JOSEPH T. CLARK, assistant surgeon.

The leave of absence granted on surgeon's certificate of disability, to MAJOR WILLIAM C. SHANNON, surgeon, Jackson Barracks, La., is extended three months, on surgeon's certificate of disability.

CAPTAIN FRANK R. KEEFER, assistant surgeon, is relieved from duty at Washington Barracks, D. C., to take effect upon the expiration of his present leave of absence and ordered to Fort Sam Houston, Tex., for duty.

FIRST-LIEUT. ALEXANDER N. STARK, assistant surgeon, upon the arrival of CAPTAIN KEEFER at Fort Sam Houston, is relieved from duty at that post and ordered to Washington Barracks, D. C., for duty.

CAPTAIN CHARLES M. GANDY, assistant surgeon, upon the arrival of FIRST-LIEUT. STARK at Washington Barracks, is relieved from duty at that post and ordered to Fort Mason, Cal., relieving CAPTAIN GEORGE M. WELLS, assistant surgeon.

CAPTAIN WELLS, on being thus relieved, ordered to Fort Ringgold, Tex., for duty.

CAPTAIN HENRY S. T. HARRIS, assistant surgeon, on being relieved at Fort Preble, Me., is ordered to Fort Washakie, Wyo., relieving CAPTAIN JOSEPH T. CLARKE, assistant surgeon.

CAPTAIN CLARKE, on being thus relieved, is ordered to Columbus Barracks, O.

FIRST-LIEUT. WILLIAM E. RICHARDS, assistant surgeon, is relieved from duty at Fort Grant, Ariz., and ordered to report September 20, 1897, for duty at Fort Apache, Ariz.

FIRST-LIEUT. WILLIAM F. LEWIS, assistant surgeon, upon the arrival of FIRST-LIEUT. RICHARDS at Fort Apache, Ariz., is ordered to Fort McPherson, Ga., for duty.

CAPTAIN WALTER D. McCRAW, assistant surgeon, upon the arrival of CAPTAIN WELLS at Fort Ringgold, Tex., is relieved

from duty at that post and ordered to Fort Thomas, Ky., for duty.

FIRST-LIEUT. BENJAMIN BROOKE, assistant surgeon, is relieved from duty at Fort Thomas, Ky., and ordered to Army and Navy General Hospital, Hot Springs, Ark., for temporary duty at that hospital.

CAPTAIN MARLBOROUGH C. WYETH, assistant surgeon, upon the arrival of FIRST-LIEUT. LEWIS at Fort McPherson, Ga., will take station at Baltimore, Md., and assume the duties of attending surgeon and examiner of recruits, relieving CAPTAIN W. FITZHUGH CARTER, assistant surgeon.

CAPTAIN CARTER, will report October 4, 1897, for examination as to his fitness for examination for promotion, and upon completion thereof, ordered to Fort Assiniboine, Mon., relieving CAPTAIN GEORGE E. BUSHNELL, assistant surgeon.

CAPTAIN BUSHNELL, upon being thus relieved, ordered to take station at Boston, Mass., and assume duties of attending surgeon and examiner of recruits.

CAPTAIN WILLIAM H. ARTHUR, assistant surgeon, will be relieved from duty at Fort Myer, Va., on October 1, 1897, and ordered to Philadelphia, Pa., and assume duties of attending surgeon and examiner of recruits, relieving CAPTAIN RUDOLPH G. EBERT, assistant surgeon.

CAPTAIN EBERT, upon being thus relieved, ordered to report October 4, 1897, for examination for promotion, and upon completion thereof, ordered to take station at Fort Missoula, Mon., relieving CAPTAIN WILLIAM D. CROSEY, assistant surgeon.

CAPTAIN CROSEY, on being thus relieved, is ordered to Fort Preble, Me., for duty, relieving CAPTAIN HENRY S. T. HARRIS, assistant surgeon.

MAJOR PAUL R. BROWN, surgeon, Fort Hamilton, N. Y., ordered to report to COLONEL CHARLES C. BYRNE, assistant surgeon-general, president of the Army Retiring Board, appointed to meet at Fort Columbus, N. Y., for examination by the board.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JULY 17, 1897.

C. G. HERNDON, surgeon, ordered to special duty at Naval Rendezvous, Duluth, Minn., July 19th.

S. B. PALMER, assistant surgeon, detached from the "Texas," and ordered to the "Annapolis," July 20th.

F. L. PLEADWELL, assistant surgeon, detached from the "Constellation," July 17th, and ordered to the "Texas," July 20th.

G. B. WILSON, passed assistant surgeon, ordered to the "Constellation."

SOCIETY NOTICE.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.—Meeting at Louisville, October 5-8, 1897. The Executive Committee met recently at Louisville, in conjunction with the Local Committee of Arrangements, the following being present: Drs. Stucky, Grant, Mathews, Love, Holloway and Reynolds. The railroads will make a round-trip rate of one and a third fare. The Address on Surgery will be delivered by Dr. J. B. Murphy, Chicago; the Address on Medicine by Dr. John V. Shoemaker, Philadelphia. Titles of papers should be sent to Dr. H. W. Loeb, Secretary, St. Louis, Mo.

BOOKS AND PAMPHLETS RECEIVED.

The Treatment of Alcoholism. By J. M. French, M.D., Milford, Mass. Reprint. 1897.

Bullet-Wounds of the Abdomen. By W. E. Parker, M.D., New Orleans. Reprint. 1895.

Original Methods for Detecting and Measuring Abduction and Adduction of the Thigh. By Phil Hoffmann, M.D., of St. Louis, Mo. Reprint. 1897.

Lesions of the Retinal Vessels, Retina and Optic Nerve, Associated with Gout. By Charles Stedman Bull, A.M., M.D. (Columbia), of New York. Reprint. 1897.

THE TUBERCULIN TEST IN TEN CASES OF ACUTE PLEURISY.

BY GEORGE G. SEARS, M.D.,
Assistant Visiting Physician, Boston City Hospital.

THAT the interest in the rôle played by the tubercle bacillus in the etiology of acute pleurisy is by no means waning is shown by the frequent appearance of papers on this subject in periodical medical literature; but the methods adopted to determine the proportion of such cases are open to the objection that they are either inconclusive or too complicated for general clinical use. These objections are only partially applicable to the employment of tuberculin, which furnishes a simple and, within certain limits, an accurate means of diagnosis. In the cases which follow, the usual initial dose was one milligramme, a larger amount being given a few days later if no reaction followed. The absence in most instances of any marked constitutional disturbance was undoubtedly due to the small size of the dose, which was selected with a view of limiting the reaction to a rise in temperature and escaping the disagreeable symptoms which are apt to follow the administration of larger amounts, as well as the possibility of waking into activity some latent tubercular focus. These ten cases have been taken as they presented themselves in the ordinary course of clinical work without thought of selection, and while the number is small the results are perhaps sufficiently striking to warrant a brief report. They may be summarized as follows:

CASE I. M. D., age thirty, hostler. Admitted to the City Hospital, June 11, 1896. No phthisical family history. He has always been well up to eight days ago when he began to complain of a "stitch" in both sides, more severe in the right, which disappeared after a few days. This was followed by vomiting, chilly sensations, considerable cough and dyspnea. Physical examination showed flatness on percussion on the right side from the second rib in front and from the spine of the scapula behind. The heart was slightly displaced to the left. The temperature on entrance was 103.2° F., but fell gradually, and remained normal after July 5th.

June 12th. Aspirated, and 84 ounces of sterile serum were withdrawn.

June 26th. For the past ten days has been growing hoarse, and can now scarcely speak above a whisper. Examination of the larynx by Dr. Farlow showed "slight intra-arytenoid thickening, dusky redness of right cord with mobility less free on that side, no ulceration, no infiltration of the epiglottis." On July 6th he was given one milligramme of tuberculin at 8 P.M. At 1 P.M. on the following day his temperature rose to 101.2° F. Constitutional symptoms were very slight.

July 27. A slight deposit still remains at the right base. Voice has improved. Discharged.

CASE II. D. C., age thirty-five, laborer. Admitted June 16th. Family history negative. Always well up to eight days ago, when he began to complain of pain in left axilla, which was followed by a short dry cough and loss of appetite. He felt feverish at night, but kept at work up to two days ago. Examination gave the characteristic signs of a left pleural effusion extending up to the third interspace in front and the spine of the scapula behind. The temperature on en-

trance was 100° F. and during the following ten days it ran a somewhat irregular course, never, however, rising above that figure.

June 19th. Aspirated, and five pints of clear serum withdrawn.

June 20th. At 6 P.M., one milligramme of tuberculin was injected, and at one o'clock on the following morning the temperature rose to 101.5° F. No constitutional disturbance was noted.

July 3d. Dulness and diminished respiration and fremitus still remains at the base. Discharged.

CASE III. J. M., age six. Admitted June 16th. Family history negative. Four days ago began to complain of pain in the epigastrium and at the right costal border, accompanied by headache, restlessness, a short cough and dyspnea. The left chest was flat throughout, and the right border of the heart was displaced a little outside the right nipple. He was immediately aspirated, and a quart of sterile serum withdrawn. The temperature, which was 103° F. on entrance, returned to normal nine days later.

July 6th. At 8 P.M., .0004 gm. of tuberculin was given; on the following day at 1 P.M., the temperature rose to 103° . This was accompanied by slight flushing, but there were no subjective symptoms. He was discharged a week later. The left side was slightly retracted, but the heart had returned to its normal place and respiration could be heard to the base.

CASE IV. D. R., age fifty-five, ragpicker. Admitted July 17th. Negative family history. Six weeks ago was attacked by sharp, shooting pains in the right side, which were followed by cough and some dyspnea on exertion. He has not, however, felt ill enough to go to bed. Examination showed an effusion in the right pleura extending to the middle of the scapula behind and the fourth interspace in front. The temperature on entrance was 99.6° F. but later it remained within practically normal limits. No bacilli were found in the sputum.

One milligramme of tuberculin was injected at 6 P.M., July 23d; and on the following day at 5 P.M., his temperature rose to 102.4° .

August 7th. Fair respiration and resonance extend nearly to the base of the chest. Discharged.

CASE V. M. M., age thirty-two, laborer. Admitted August 4th. Family history negative. Has always been strong, but has lately been subject to a winter cough. Two years ago had "chaneroids." Three weeks ago, after exposure, he had a sudden severe pain in the right side, which was increased by coughing or drawing a long breath. He became thirsty and feverish, and had to give up work. For the past week he has had diarrhea. The physical signs were a counterpart of the preceding case. No evidence of syphilis was found. The temperature on entrance was 100° , but it rapidly returned to normal and remained there.

August 12th. Tuberculin (.001 gm.) was injected at 6 P.M. At 1 P.M. on the following day, the temperature had risen to 102° , and at 5 to 103° . The pulse and respiration were both accelerated, and there was some general discomfort.

August 19th. Slight dulness still remains over the lower portion of the right lung, but fremitus and respiration are present to the base. Discharged.

CASE VI. B. M., age fourteen. She was admitted August 6th. Mother is now ill with consumption.

Has never been very strong, and for about a month has been losing strength and flesh. Two weeks ago slept in a draft, and on the next day she began to complain of pain in the right side, which was increased by breathing and accompanied by cough with a little expectoration. The patient was a pale, poorly nourished, rather phthisical-looking girl. The heart was displaced to the left, and the right chest was completely filled with fluid. The temperature on entrance was 102.2° , and it remained somewhat irregularly elevated up to the 26th.

August 20th. One milligramme of tuberculin was injected, and in the following afternoon the temperature rose to 101° , which was slightly higher than usual; but it was probably a coincidence, as three milligrammes three days later had no appreciable effect.

August 31st. Considerable dulness still remains at the base, and fremitus is still absent, but respiration can be heard to the bottom of the chest. The temperature has been normal for five days, and patient feels much better. Discharged at own request.

CASE VII. J. B., age twenty-six, carpenter. Admitted August 9th. Two sisters died of pneumonia. Patient probably had syphilis several years ago. Has not felt as well as usual for the past year, probably attributable to alcohol, as he has been drinking hard. Two days ago, while in bathing, was very nearly drowned and felt much exhausted after being rescued. The following day he was taken with a severe pain in the right axillary region, followed by nausea, vomiting and dyspnea. On entrance marked friction was heard over the lower right front, which was later replaced by signs of effusion occupying the lower half of the right chest. The temperature remained elevated, (highest point 101.5°) for about three weeks. Tubercle bacilli were not found.

September 2d. A rise of one degree followed the injection of .001 gramme tuberculin.

September 6th. At 7 p. m., .005 gm.; at noon on the next day the temperature had risen to 102° , and patient felt so ill that he went to bed.

September 11th. Except for slight dulness, the signs have all disappeared. Discharged.

CASE VIII. P. M., age twenty-one, laborer. Admitted August 29th. Family history not known. Always well up to three weeks ago, when he began to feel poorly owing to pain in the right chest, cough, dyspnea and headache; but he managed to keep at work up to a week ago. The whole right chest was dull on percussion. The voice, the vocal resonance and the respiration diminished downward, and were lost toward the base. A coarse, leathery friction sound was heard over the upper portion of the front as low as the sixth rib, and also in the lower axilla and in the back. The temperature on entrance was 101.4° ; and it ran a somewhat irregular course during his stay in the hospital, never, however, exceeding 100° .

September 6th. Twenty-five ounces of bloody fluid were withdrawn by aspiration.

September 5th and 7th. Tuberculin (.001 gm.) was given, with no appreciable effect; but .005 gm. given on the 8th caused a rise of temperature to 102.4° within eleven hours. Constitutional disturbance was not marked.

September 11th. Signs of a slight deposit at the right base still remain. Discharged.

CASE IX. H. N., age thirty-six, washerwoman. Entered December 29th. One sister died of "lung trouble." Has always been well up to ten days ago, when she had a chill, with sharp pain in the left side. The expectoration was bloody for the first three or four days. The left chest was dull over its lower two-thirds, with faint bronchial respiration and diminished to absent fremitus. The heart was considerably displaced. The temperature was 102° , returning to normal by lysis on January 6th.

January 8th. Tuberculin (.003 gm.). On the following evening the temperature rose to 101.5° .

January 14th. Tuberculin (.005 gm.) in the morning. At 1 a. m. the following morning the temperature rose to 102.4° . Constitutional symptoms were slight.

February 3d. The signs at the left base have almost disappeared. Discharged.

CASE X. M. L., age eighteen, milliner. Admitted January 13, 1897. One brother died of consumption. Three weeks ago she "caught cold," and began to complain of pain in the lower portion of the left chest in front. She became somewhat feverish, and after a few days began to cough; but she kept at work up to four days ago, when she was obliged to give up, owing to the increasing dyspnea. The left chest was dull throughout, and flat from the second rib in front and from an inch below the spine of the scapula behind. The heart was displaced nearly to the right nipple. The temperature remained elevated for the first two weeks of her stay.

January 17th. Aspirated, and one pint of clear serum withdrawn.

January 29th. Three milligrammes of tuberculin were injected, and within four hours the temperature rose to 104° . Constitutional symptoms were very marked.

February 8th. A slight deposit still remains at the base. Discharged.

Of these ten cases one-half at least had no hereditary taint, and eight were in their normal state of health when they were suddenly attacked by the disease without discoverable cause other than a possible exposure to cold or wet. Of the remaining two the history in one of bloody expectoration suggests the probability that the pleurisy was secondary to pneumonia, while in the second the association with a consumptive mother and the gradual loss of strength and weight during the previous month gave ample ground for suspecting a tubercular infection; yet in every case but the latter the temperature, which had been normal or practically so for several days, showed on a four-hourly chart a well-marked rise, within twenty-four hours, varying from 101° to 104° , and then rapidly fell to its former limits, and in that case a larger dose might have been followed by a reaction, but she left the hospital before an opportunity of proving it was given.

Case VII also deserves a word of comment from the presence of an earlier history of syphilis, which is also said to react to tuberculin. In the two or three cases, however, of late syphilis in which I have tried it no effect has followed the use of similar doses.

Although convinced that tuberculosis is a very common cause of acute pleural inflammations, I was not prepared for so high a percentage, which far exceeds any figures with which I am acquainted when the

results were based on bacteriological investigations. The nearest approach to it is in a series published by Eichorst where he got positive results in 15 out of 23 cases by inoculating guinea-pigs with the aspirated serum. It is, however, nearly identical with the results obtained in a series of 15 cases quoted by Netter, where 13 reacted to the tuberculin test. Combining the latter with the 10 cases here reported a total of 25 is given, of which 22 showed a positive reaction. But if tuberculin is the delicate reagent which it is claimed to be, and which there is good reason to suppose it really is, these figures cannot be accepted as an absolute criterion of the proportion of idiopathic pleuritis in which the tubercle bacillus is the etiological factor, since the possibility cannot be eliminated that they might be due to a coincident infection with some other organism of patients with a latent tubercular focus in some other portion of the economy, to which the reaction was due, and which would be a source of error whose importance could not be estimated.

Before closing a word should be said as to the reported dangers arising from the use of tuberculin as a diagnostic agent, about which much has been written. My experience in its administration for such purposes is limited to about 40 cases; but so far as it goes it shows that none is to be apprehended when it is given in doses only large enough to lead to an elevation of temperature. Such a dose rarely needs to exceed one milligramme, and frequently less than that quantity is sufficient.

THE DIAGNOSTIC VALUE OF TUBERCULIN.*

BY FRANKLIN W. WHITE, S.B. M.D., BOSTON.

DURING the past year, at the suggestion of Dr. F. C. Shattuck, a series of observations were made at the Massachusetts General Hospital to determine the diagnostic value of tuberculin injections. The injections were given to 123 ward patients, all adults, with the exception of one child of two years; 93 of these cases I report from personal observation; the results of 30 subsequent injections made by Dr. J. A. Capps are reported from the hospital records.

In selecting cases for injection, only those patients who were *afebrile*, or nearly so, and whose physical condition was fairly constant from day to day, were considered suitable.

In addition to the usual daily chart of the patient's morning and evening temperature, a four-hourly chart was kept, beginning at least twenty-four hours before the injection and continuing for several days after it. The injections were made with an ordinary hypodermic syringe, which was sterilized each time before using, by boiling the needle, and filling the syringe with 95 per cent. alcohol. The solutions used were 1 to 1000, 1 to 500 and 1 to 100 dilutions of Koch's tuberculin in distilled water, the solutions being made up freshly every day or two.

The injection was made, as a rule, deep into the muscles of the back or thigh. In 18 cases the injection was made subcutaneously in the arm; in some of which a local inflammation occurred which completely disappeared in a few days. The *deep* injection

is preferable, never producing any local phenomena beyond a slight stiffness in the muscles the day after injection, in about one-half the cases.

The doses of tuberculin given were one, two, five, seven, and ten milligrammes, obtained by giving one-half to one cubic centimetre of the above-named dilutions. At first, to avoid any possibility of an overdose, an injection of one or two milligrammes was given; and if this produced no reaction, it was followed in two or three days by an injection of 10 milligrammes. In a few cases, an initial injection of five or seven milligrammes was given. After treating about 35 cases in this way, it was found that the one and two milligramme doses could *not* be relied on to produce a reaction in tuberculous cases, and that the ten-milligramme doses had given no bad results; so the small, preliminary doses were omitted in the remaining cases.

Three tuberculous cases, which were given doses of five milligrammes, reacted promptly. As a rule, ten milligrammes of tuberculin were given at one dose for the sake of uniformity and to avoid the remarkable "tolerance" which is speedily established by the use of small repeated doses, and because it was believed that a dose of ten milligrammes would give a more definite characteristic reaction, both as regards temperature and constitutional disturbance, than a single dose, one-third or one-half as large.

There is much diversity of opinion about the size of dose which is most desirable in diagnostic work. Koch¹ says in his early articles that the smallest quantity requisite to produce an effect in healthy individuals is about ten milligrammes, that phthisical cases are more susceptible than surgical cases, and react to one or two milligrammes, and that tuberculous children react to one-half or one milligramme. Berthenson² states that one milligramme usually produces a fair reaction in tuberculous adults. Grasset³ used two-tenths or three-tenths for a first dose and if no reaction followed, five-tenths of a milligramme for a second dose, and believes that these small doses are useful in diagnosing early cases. There is, however, one serious objection to small repeated doses. Grasset, Neisser⁴ and Von Ruck⁵ admit that the patients may become habituated to them, and cite a number of cases of phthisis treated in this way without reaction.

Von Jaksch⁶ says ten milligrammes is too large a dose for diagnostic purposes, that five milligrammes is better. Speaking of children, Gattie⁷ advises the use of a dose of one-twentieth of a milligramme. Kossel¹⁰ used two-tenths to one milligramme as a first dose, and if no reaction occurred, gave five or ten milligrammes two days later. As the temperature of children is very variable and easily affected by slight causes, he recommends a repetition of the dose causing reaction in all cases to be sure the temperature was due to the tuberculin.

The discrepancy in the size of the dose advised by different men may, perhaps, be partly explained by possible variation in the strength of different samples of tuberculin. There are, apparently, a number of conditions apart from the amount of tubercular process present upon which the febrile reaction depends, such as:

- (1) Individual disposition.
- (2) Size of dose.
- (3) Habituation of the patient to tuberculin.

* Read at a meeting of the Clinical Section of the Suffolk District Medical Society, March 17, 1897.

(4) Sex. Ruedi⁸ asserts that females react less readily than males. Our results do not confirm this statement.

(5) Time of injection. Rosenbach⁹ says that the febrile reaction after an injection in the morning is more prompt, higher and shorter than after one in the afternoon. In our cases, almost all the injections are made about 8 p. m. for convenience, and the reactions are of the type Rosenbach describes as "late reactions," slow in onset and long in duration, the temperature rising about eight and one-half hours after injection, and falling to normal after about twenty-nine hours. Compare this with Koch's description of a "typical reaction" with a temperature rising four or five hours after injection and lasting from twelve to fifteen hours.

There have been no bad results from our injections, the worst being a condition resembling a "touch of grippé," usually lasting a little over twenty-four hours in the reacting cases. No definite changes in local tubercular processes were, as a rule, discovered after the single injection. In classifying the cases, we arbitrarily define a "reaction" following injection as a condition of fever of 101° or over, associated with the ordinary febrile symptoms, general malaise, headache, anorexia, pain in the back, etc. In giving the injections to patients whose temperature and general condition was tolerably stable, the "reacting" patients were very readily distinguished from the "non-reacting" by the abrupt rise of temperature and constitutional disturbance following several hours after injection.

One hundred and twenty-three patients were injected with tuberculin, 45 of whom were tuberculous, 8 of whom were classed as "doubtful" and 70 of whom gave no clinical evidence of tuberculosis.

Reactions were obtained in 66 cases (see tables).

In 66 cases after	10 milligrammes.
In 1 case after	7 "
In 3 cases after	5 "
In 2 cases after	2 "

The temperature began to rise eight and four-tenths hours after injection.

The averages of the reactions in 66 cases are as follows:

Average maximum temperature	102.8
Average maximum pulse	115
Average maximum respiration	31
Average duration of fever	29 hours.

The following figures give the limits of variation in the reactions:

Longest period after injection before rise of temperature	24 hours.
Shortest period after injection	1 hour.
Highest maximum fever	106.2
Lowest maximum fever	101
Highest maximum pulse	160
Lowest maximum pulse	88
Highest maximum respiration	60
Lowest maximum respiration	29
Greatest duration of fever	81 hours.
Least duration of fever	12 hours.

On arranging results by sexes, we find that 68 males were injected, 36 cases or 53 per cent. reacted, with an average maximum temperature of 102.7°, and an average maximum pulse of 108; 55 females were injected, 30 cases or 54 per cent. reacted, with an average maximum temperature of 103° and an average maximum pulse of 123.

Now, considering the reacting cases in detail, we

find that a well-marked reaction was obtained in 29 cases where excellent evidence of tuberculosis was present, comprising:

Ten cases of phthisis with tubercle bacilli in sputa.

Eleven cases of bone and joint tubercle.

One case of skin and two of glandular tuberculosis.

Five cases of tubercular peritonitis.

Also, in 16 cases where the presumptive evidence of tuberculosis was very strong, comprising:

Three cases with a clinical diagnosis of phthisis, but without tubercle bacilli in sputa: one of these with a family history of phthisis, crackles and dulness at apex, sweats, loss of weight; one with pulmonary hemorrhages and signs at apex; one with cough and signs at apex, in bed seven months.

Four cases of chronic pleurisy: one with cough for

two years, sweats and loss of weight; one with loss of weight and crackles at apex.

Seven cases of acute pleurisy: one with bloody fluid and crackles at apex; one with a tuberculous knee eighteen years previous; one with a family history of phthisis; one with loss of weight and previous cough.

One case of salpingitis, with tubercular family history, signs at apex and loss of 40 pounds weight.

One spinal caries, with lumbar antero-posterior curvature with pain and tenderness.

Forty-five cases in all.

Reactions were obtained in a considerable number of cases where absolute evidence of tuberculosis was not obtainable, in one each of bronchitis, chronic meningitis, cerebral tumor, chronic diarrhea, salpingitis, rheumatoid arthritis, gastric dilatation, enteritis, chlorosis, abdominal tumor and spastic paraplegia; in two cases of thigh fracture and in eight cases of debility; 21 cases in all. Eight of these cases we class as "doubtful," as each may be fairly suspected of tuberculosis, but none give absolute evidence. We have drawn no conclusions as to the diagnostic value of the method from these cases. They comprise four cases of debility (two with tuberculous family history, one with cough for six months, one with cough for four months, sweats, loss of flesh, and having a tuberculous wife and child), also one case of salpingitis, one chronic meningitis, one chronic diarrhea, and one cerebral tumor.

The remaining 17 cases have nothing indicating tuberculosis in family or personal history (except debility and the loss of flesh) or on physical examination.

Adding these 13 cases to the 57 non-reacting cases, we find that of 70 patients giving no clinical evidence of tuberculosis, 18.5 per cent. reacted. It is fair to assume from these facts that tuberculin will cause a reaction in some non-tuberculous cases; and, on the other hand, this class of cases would probably be much smaller in our lists if we were able to rule out all cases of possible glandular or incipient pulmonary tuberculosis in which the reaction to tuberculin is the only evidence we have of the presence of the bacillus. To illustrate the small value of clinical evidence of some cases, we quote the following series: Kossell,¹⁰ speaking of 28 reacting cases among children of one to ten years of age, in only four of which clinical evidence of tuberculosis was present, says that in accordance with his experience at autopsies in such children, at least two-thirds of the remaining 24 cases are to be considered as tuberculosis of the bronchial or mesenteric glands.

Many writers report cases of reaction in the so-called non-tuberculous, some after small doses. For example, Kohler and Westphal¹¹, Leyden¹², Peiper¹³, Auerbach¹⁴, Post¹⁵, and Maydl¹⁶ report collectively over 30 cases reacting to doses of one, two, three and five milligrammes, and a number of other cases reacting to larger doses.

Granting that these cases reacting to doses of tuberculin as small as one or two milligrammes were really non-tuberculous, it is evident that we can hardly expect to ever make the injection test an absolute one; even when we have determined the smallest reliable dose for tubercular cases, we shall probably find occasional non-tuberculous individuals who will react to it.

In 57 cases † tuberculin was injected without reaction. In most of these cases the injection was made simply to test the method upon the non-tuberculous. In a considerable number of them it proved useful in making a diagnosis, which was confirmed by operation, or by the subsequent history of the case. There is no evidence of tuberculosis in a single non-reacting case.

As instances of its use in diagnosis, we cite the following non-reacting cases:

A case of supposed tuberculosis of the mesenteric glands failed to react; an operation proved it to be retro-peritoneal sarcoma.

A case of ascites, supposed to be tubercular peritonitis, failed to react; an operation showed no trace of tuberculosis in the abdomen.

A case of supposed hip-disease, with pain and stiffness, failed to react; subsequent history showed it to be an hysterical hip.

A case of marked general debility and anemia failed to react; blood examination showed it to be a progressive pernicious anemia.

Four cases of bronchitis failed to react; the lungs cleared up and the patients were discharged well.

Nine cases of general debility failed to react; all the patients were later discharged well.

It is interesting to note, in connection with the possible tubercular origin of acute serous pleurisy, that seven out of the eight of these cases reacted; four chronic pleurisies also reacted. In two of these reacting cases (one acute, one chronic) there were signs of incipient disease at one apex.

In looking over our results, we see that a well-marked reaction was obtained in every case where evidence of tuberculosis was present, and in a little less than one-fifth of the patients in whom no evidence of tuberculosis was obtainable.

We might infer from these results that the presence of a reaction after tuberculin indicates the presence of a tubercular process about four times out of five, and that the absence of a reaction indicates an absence of any tubercular process in the patient injected. We cannot, however, insist on this last statement in view of the results of other observers. All our cases of tuberculosis have reacted; whether this was due to the method of giving a single good-sized dose of tuberculin or to the limited number of the cases, or to the fact that very few were advanced cases, it is impossible to say. Previous writers have reported occasional rare and usually advanced cases of undoubted tuberculosis without reaction.

Berthenson² reports two cases, and Heron¹⁷ one advanced case of tuberculosis, with a fall of temperature after each injection. Ruedi⁸ reports an advanced case where constitutional and local reaction were present without any febrile reaction. Braun¹⁵ reports one advanced case. Post gives¹⁵ one advanced case, and Bobrick¹⁹ two advanced cases of tuberculosis without general reaction. Neisser⁴ says that old lung cases may react only locally.

In our experiments the general febrile reaction has been chiefly studied and regarded as the most reliable diagnostic phenomenon; and on this basis, the tuberculin injection for diagnosis is of least value in ad-

† These patients consist of cases of debility, rheumatism, neuralgia, anemia, convalescents from acute infectious diseases, fractures, bronchitis, serous pleurisy (one acute case), chorea, gastric ulcer, cancer of stomach and liver, ascites, pregnancy, salpingitis (gonorrheal), pyelitis, laryngitis, nephritis and gall-stones.

vanced cases, where, as is well known, the general reaction is slight and the local reaction marked, and is *most sure* where it is at the same time *most useful*, namely, in *early cases* which give a marked general and slight local reaction.

The difficulty or impossibility of observing the local reaction in many cases, especially the early ones, renders it of little value as a diagnostic point.

Objections have been raised to the use of tuberculin, even for diagnostic purposes, on the ground that there may be danger of poisoning the patient, or of stirring up latent tubercle bacilli and offering them a better opportunity for growth. We can only say that the method of diagnosis in our hands has been productive of no ill results, as far as we know, beyond a day's discomfort to the patient, and that the occasional dangers of continued tuberculin treatment of tuberculosis in general, including advanced cases, have not been met with in using a single dose of tuberculin for diagnosis in incipient cases. When we see the brilliant results obtained in the diagnosis of tuberculosis in cattle by this method, a correct diagnosis in over 99 per cent. of the cases, it seems as if a further experience in the observation of the reactions and a better knowledge of the most desirable dose were all that were necessary to make this a diagnostic method of the greatest value for man. It was a great advance when Koch gave us the method for finding the bacillus of tuberculosis, but before the diagnosis can be made by the microscope, it can usually be made without it. When we find the bacilli, our diagnosis is certain; but failure to find them does not exclude the disease. The tuberculin test is much more helpful in early diagnosis. An injection will show the presence of the bacilli long before the inflammatory process is apparent to sight or touch; and on the other hand, a negative result gives absolute surety of freedom from tuberculosis, which of itself is often of the greatest value.

We will summarize briefly as follows:

- (1) The tuberculin method is simple and easily applied. An absence of reaction after injection indicates almost invariably an absence of tuberculosis. The presence of a reaction indicates the presence of tuberculosis more than four times out of five.
- (2) The method is especially applicable to the diagnosis of incipient pulmonary tuberculosis and of glandular, peritoneal, pleural and bone tuberculosis, where the bacilli cannot readily be found.
- (3) The general febrile reaction is a more generally useful diagnostic phenomenon than the local reaction.
- (4) The use of small preliminary doses of tuberculin is to be avoided on the ground of producing a gradual tolerance and a loss of general reaction.
- (5) The size of the best dose for diagnostic work is a matter for further study. It is probably between five and ten milligrammes for adults.
- (6) Ruedi's statement, that females react to tuberculin less readily than males, has not been confirmed by our results.

SOME CASES OF CYSTITIS IN WOMEN.¹

BY EDGAR GARCEAU, M.D.,

Surgeon to Out-patients, Free Hospital for Women, Boston; Clinical Instructor in Gynecology in Tufts Medical School.

(Concluded from No. 5, p. 100.)

CASE V. Acute nodular cystitis, purulent endometritis, fistula in ano, patulous meatus. Symptomatic cure in two weeks. Persistence of vesical lesions notwithstanding symptomatic cure.

Mrs. D. was a woman, forty years old, who had had three children and six miscarriages. She gave a history of ischio-rectal abscess, which left a fistula. Three weeks before examination she was attacked by frequent painful micturition, which compelled her to seek advice.

On examination the fistula was observed, and also a purulent discharge, which proceeded from the uterine cavity and bathed the meatus with pus. The pus had no difficulty in finding ready access to the bladder through a meatus which was markedly *patulous*. Cystoscopic examination showed a bladder which was greatly inflamed. The urethra, vesical neck, trigonum, and ureteral eminences were much injected, and on the eminences were several small yellow points. The blood-vessels of the bladder were all injected, and scattered about here and there were many nodules of hyperemic appearance. The whole wall was cloudy looking. The infection had evidently proceeded from the purulent endometritis. The treatment was, for a month, nothing but a mixture of equal parts of fluid extract of buchu and tincture of benzoin compound taken internally. Under this she improved so that at the end of a week from the time of beginning treatment she was completely cured symptomatically, and was urinating only three times a day and not at all at night.

In order to be sure that the bladder was normal, in view of the rapid cure taken in connection with the severe inflammation, another examination, a month after beginning treatment, was made, with the result that the appearances were found to be exactly the same as at the first examination. She then had injections of permanganate of potash solution; and these were continued for a period of two months, when another examination was made. The appearances had altered but little. There was perhaps a slight diminution in the degree of injection, but the nodules remained and the cloudy appearance as well. It looked like a severe case of cystitis. But on examining urine obtained with the catheter, it was found to be free from pus, in this respect differing from the urine at the outset of the disease. No more treatment is now being given, except that directed to the purulent endometritis. In order

¹ Read before the Gynecological Section of the Massachusetts Medical Society, February 24, 1897.

to avoid a relapse she was advised to undergo an operation for the cure of the fistula and the endometritis.

The condition of patulous meatus is one which demands some consideration, inasmuch as the author believes that this condition favors the development of cystitis.

The normal meatus is closed by two labia or eminences of its own, of small size, one on each side, as described by Skene.¹³ Further closure is effected by the mucous membrane of the upper urethral wall, which prolapses between the two labia, and helps still further to keep the meatus closed. Besides this, Luschka's sphincter, situated behind the vestibule closes the urethra still more effectually.

The author has never failed to find these labia in women who have not borne children; and a cystitis in such women, in the absence of lesions of neighboring organs, especially if of long duration, is looked upon as of renal rather than of local origin, for reasons which will be explained. In women of the child-bearing period these labia are frequently obliterated, and Luschka's sphincter stretched, so that a patulous condition of the meatus is present. This obliteration must be brought about by the stretching and laceration of the meatus during the passage of the child's head, or what is more frequently the case, a lacerated perineum leading to prolapse of the pelvic contents and finally of the urethra, and secondarily, to eversion of the mucous membrane of the urethra.

In old age the general atrophy of the genital organs does not spare these labia, for the author has frequently found them quite absent in old women, and the meatus presenting as a small pit with dry mucous membrane lining it.

If there is a purulent vaginal discharge under these circumstances, which constantly bathes the patulous meatus with germs, it is easy to see that entrance to the bladder might be more readily effected than if the meatus were closed as it is under normal conditions. It seems not improbable that the function of Skene's glands must be to secrete a fluid which is antiseptic in its properties. This idea was suggested to the author from the fact that the vaginal glands have a decidedly destructive power over germs, as proved by Barton Cooke Hirst. In a patulous meatus this secretion is no longer concentrated in a small space, but must be scattered over a larger area; and in cases of considerable patulousness the secretion must necessarily be spread laterally, as the openings of these glands are at the bases of the labia and the latter are everted outwards in a patulous condition.

The normal urethra is thus well protected from the invasion of germs. This is necessary from the fact that the vulva normally may be covered with germs, which, were there not some obstacle to their entrance to the bladder, would cause cystitis more frequently than they do. This seems to be proved by observations on children. Thus Trumpf,¹⁴ in studying cystitis in young children, found only 29 cases out of presumably a large number, for he concluded that cystitis in children is rare. All the children were from five weeks to three years old, at an age when diarrheal discharges would be spread over the vulva at each stool. All the children had diarrheas, and in all the cases except one the bacterium coli was found. Trumpf thinks that the infection took place through the urethra or

through the lymphatics. The rarity of the disease in children, when it is considered that the vulva is bathed almost constantly with the bacterium coli bacillus in conditions of diarrhea, would seem to prove that there exists an obstacle to the entrance of the germs into the urethra. This favors the view that the infection in these cases is through the lymphatics.

The sequence of events in the causation of cystitis may be the following: Childbirth, lacerated perineum, genital prolapse, patulous meatus, endometritis, and finally cystitis. In old women, in whom cystitis is by no means uncommon, the disease may be caused by a senile endometritis, or vaginitis, the infection being likewise introduced through a patulous meatus. It will now be understood why a cystitis in a *virgo intacta*, especially if the cystitis is of long standing, should excite the suspicion of renal origin; and in young girls with a tubercular history the ureteral catheters should be introduced without delay in order to discover which side is affected, so that the kidney may be extirpated at once.

CASE VI. Intermittent cystitis of eleven years' standing; hematuria; suspected renal calculus, photographed by x-rays, result negative.

Mrs. P., a married woman sixty-seven years old, began eleven years ago to pass blood-red urine. The hematuria came on suddenly, coincidently with some dyspepsia and some backache. This condition lasted a little while and gradually disappeared. Then there was an interval of five years, during which the urine was normal in color. The hematuria now reappeared suddenly, and lasted seven months; during this time so much blood was lost as to render the patient quite anemic, and she lost strength rapidly. During this attack pain was complained of, for the first time, in the left hypochondrium anteriorly. Under tonic treatment she gradually got better, and the red color in the urine disappeared. Then there was a period of rest for seventeen months; at the end of this time, which was in May, 1893, there was another attack of hematuria, and also severe pain in the left lumbar region, shooting up to the neck. The pain was so severe as to prevent sleep. This time the hematuria lasted six months. The amount of blood was never large, but it was enough at times to stain the urine quite red. The color was uniform, and there was no increase of color towards the end of urination. The bladder was now quite irritable, and she suffered a good deal from dyspepsia. The urine showed pus, blood, granular casts, and a few calcic-oxalate crystals. Exertion always increased the amount of blood in the urine.

In October of 1893 there was an attack of catarrhal jaundice. An examination of the urine, now quite pale, showed a distinct pus cast of large diameter. The lumbar pain was still present.

In June, 1894, she was fairly comfortable, with the exception of dyspepsia, which gave great suffering. Urine still contained a large amount of pus, but very little blood.

In July, 1895, she reported herself as quite well; no hematuria for a year, but pains in lumbar regions were still present.

In November, 1896, she was suffering somewhat from the pain. She noticed that when the sediment was abundant in the urine the pain was less. Dyspepsia continued. An examination made at this time showed some resistance over the left lumbar region, but no tumor. The meatus urinarius was markedly

¹³ Skene: Diseases of Women, 1889, p. 614.

¹⁴ Trumpf: Kinder Arzt., vol. vii, No. 10.

patulous; vesical neck, sensitive; ureters on vaginal examination, not enlarged. Cystoscopic examination, rather unsatisfactory on account of nervousness, showed cystitis; urine contained much pus, but no casts were found. The cystitis was giving a great deal of trouble and the urination was frequent and attended with tenesmus. There had been no hematuria for two years. The bladder was now treated with permanganate-of-potash injections, and great relief given, but the pus persisted.

January 8, 1897, an examination showed the presence of an occasional cast and calcic-oxalate crystals; the latter had almost always been found in the sediment. A quantitative examination of the urine showed that the kidneys were doing an insufficient amount of work. Thus the amount of urine in twenty-four hours was only 900 c. cm.; urea, 11.34 gms.; phosphates, .765 gms.; chlorides, 6.66 gms.; total solids, 27.26 gms.; specific gravity, 1.013; albumin, a trace; sugar, absent.

At the present writing the patient is better; but the cystitis persists and the pus in the urine is in as large amounts as it was two years ago. No local treatment will check it. It is thought to be renal in origin. Suspecting a renal calculus, the patient was photographed by Dr. E. A. Codman, with the x-ray apparatus; the exposure was half an hour. The result was entirely negative, however, for no shadow was seen indicative of stone. This result was rather expected, however, for photography of renal calculi by the x-ray has been hitherto very unsatisfactory. Still Swain¹⁵ photographed a renal stone of calcic oxalate before operation, and at operation a stone weighing 148 grs., was found. Macintyre¹⁶ had five cases in which renal stone was suspected, but in none was a photograph of the stone secured. It is not stated if the cases were operated on subsequently. But in experiments on a cadaver this author succeeded in getting a picture of a uric-acid calculus inserted in the kidney. Raw¹⁷ performed the same experiments, and got a picture of the stone after an exposure of sixty minutes. Laurie¹⁸ performed the same experiments, and got a picture with an exposure of thirteen minutes; in his case the stone was uric acid. This result seems remarkable, for, according to Laurie's experiments, uric acid is very slightly more opaque to the x-ray than flesh, calcic oxalate and phosphate-of-lime stones being much more so.

In view of the contradictory evidence thus furnished, failure to secure a photograph of the stone need not be considered as proving that the stone is not present. The picture of even the spinal column and ribs when taken with the x-ray is very indistinct, and requires careful examination to even make it out. It can readily be conceived, therefore, that a small stone weighing a few grains, and located in the renal pelvis, might easily escape detection. Such a stone was reported by Kelly.¹⁹ The history was one of persistent pyuria for ten years. The diagnosis was made by inserting a long renal catheter up to the pelvis of the kidney, when at once more urine flowed through the catheter than on the normal side in the same time, showing that there was some obstruction which acted as a ball-valve at the mouth of the ureter.

Confirmatory evidence was furnished by finding bits of uric acid in the eye of the catheter when suction with an aspirator was employed. A small stone 11 by 16 mm. was found in the renal pelvis at the operation. Thinking this might be a similar case, it was proposed to the patient to have the ureters catheterized. But the proposition was rejected, so that this valuable aid has to be dispensed with.

The history of the case is strongly suggestive of renal calculus. The persistent presence in the urine of calcic oxalate favors a diagnosis of this sort of stone; but inasmuch as calcic oxalate is so frequently found in debility of any kind, the presence of calcic oxalate in the urine does not carry with it that weight which it would if such were not the case. It is to be remembered also that oxaluria associated with severe lumbar pain is possible and yet no stone may be present in the kidney.²⁰ A simple pyelitis is improbable from that fact of the copious hemorrhages, yet it cannot be absolutely excluded. Uncomplicated cystitis is improbable from the nature of the hemorrhages, the red color having been uniform; while the other symptoms point to a renal rather than a vesical origin.

It is unfortunate that the patient refuses to allow catheterization, for there is every reason to believe that a positive diagnosis could thereby be made. If a simple purulent pyelitis were present, it could be treated locally by irrigating the renal pelvis by means of the long renal catheters; while if it were possible to diagnose calculus, an incision could be made for its removal.

From the study of these cases it is evident that cystitis may be merely a complication of more serious disease of the kidney, and that the symptoms of renal disease, if present at all, may be quite overshadowed by the annoying vesical affection. Not only in the early stages of renal disease may symptoms be entirely wanting with reference to the kidney, but likewise in late stages when the kidney is entirely disorganized, as in Case IV. In this case there was no pain in the kidney, nor other sign denoting the late stage of the disease, and the symptoms were entirely vesical. There is danger, therefore, that the bladder may receive all the attention on the part of the physician, while the focus of the trouble, the kidney, giving no symptoms, may be allowed to continue in the destructive process going on within it, which renders unavailing any treatment directed to the bladder. It is the author's belief that hitherto many of the failures to cure cystitis, even after cystotomy and prolonged drainage, are accounted for by the fact that constant re-infection of the bladder is produced by germ-laden pus proceeding from a suppurating kidney which through lack of symptoms has been undetected.

It is of the utmost importance, therefore, that the condition of the kidneys should be ascertained in cases of cystitis, in order that the treatment may be appropriate to the case. This is readily accomplished by drawing off the urine by means of the ureteral catheters inserted into each ureter through a Kelly cystoscope, and by subjecting the urine obtained from each kidney to microscopical and chemical examination. Only two cubic centimetres of urine are required to estimate, by Knop's hypobromite method, the percentage of urea; and this gives the exact working efficiency of the respective kidney; while examination of the sedi-

ment in the rest of the urine drawn gives valuable indications of the processes going on in the renal substance. Besides this, it is possible to determine by this means whether both kidneys are present or not. But it is not urged that indiscriminate catheterization of the ureters is to be done, and the question when to catheterize the ureters and when to refrain from doing so is an important one. The danger of infecting a healthy ureter or kidney by means of the catheter should not be overlooked. In deciding this point *acuteness* or *chronicity* of the disease must be considered, as well as *source* and *nature* of infection.

In the acute cases catheterization is not necessary, except in cases of suspected early renal tuberculosis. In a young, unmarried girl, with a non-patulous meatus, and with no local purulent affection of the genital organs, a cystitis of no discoverable etiology must always be looked upon with suspicion. If in such a patient there is evidence of tubercular disease elsewhere in the body, especially if there is a family history of phthisis, the urine should be examined at once for bacilli of tuberculosis. If these are found, it is presumptive evidence of renal tuberculosis; as primary vesical tuberculosis is rare,²¹ ureteral catheterization is imperative in order that the kidney may be extirpated at once. After the nephrectomy has been performed, the bladder may be treated locally through the cystoscope, and a favorable result looked for. In the chronic cases of cystitis the question may be more difficult to decide. Either the inflammation is strictly local and does not affect the ureters or kidneys, or else the infection of the bladder has proceeded from an infected kidney, and is therefore not primary but secondary in importance. A careful study of these cases is essential, and the ureteral catheters should not be introduced without due deliberation. An inflammation which has been caused by germs introduced through the urethra is probably confined to the bladder alone. The etiology must, therefore, be sought. A patulous meatus associated with a purulent vaginal discharge is sufficient evidence of source and nature of infection; so also is a history of gonorrhea; or a catheter infection; or an infection due to rectal disease and carried to the bladder by means of the lymphatics. If such a cystitis is not of too long duration, ureteral catheterization must not be resorted to. At the same time it is necessary to consider the probability of extension upwards of the inflammation into the ureters and kidneys. In long-standing cystitis this is very apt to be the case; so that ureteritis, single or double, is not an uncommon occurrence. This is one explanation of failure to cure cases of cystitis by cystotomy; and it would seem not unreasonable to catheterize the ureters of all patients before subjecting them to this operation with its attendant disagreeable features. The diagnosis of ureteritis without catheterization is very uncertain. The most positive sign is a thickened ureter felt vaginally; but if the thickening is too high up to be felt, it escapes notice. Much stress has been given to the fact that in ureteritis the mucous membrane of the ureter is apt to become everted at the vesical orifice and to present as a reddened mass of mucous membrane. But this is not a positive sign, for in at least two cases seen by the author, there was no such prolapse of the ureteral mucous membrane, and yet catheterization showed evident ureteritis.

When the source of infection is the kidney, the previous history of the case will sometimes throw light on the diagnosis, and may furnish enough evidence to warrant ureteral catheterization. Thus a history of persistent lumbar pain, lasting many months and accompanied by attacks of renal colic and hematuria, is presumptive evidence of renal calculus. Under these circumstances catheterization may furnish valuable aid in making a diagnosis. In the case of abscess of the kidney in which an abundant amount of pus is discharged into the ureter, a diagnosis can sometimes be made by seeing, through a cystoscope, the pus exude from the ureteral orifice; in these cases it is of value to catheterize the ureter in order to obtain urine so that the percentage of urea may be calculated. If a large amount is present and the affection is not tubercular, the treatment would be more intelligently given than if the working power of the kidney were not known; an attempt might be even made to cure the affection by washing out the abscess cavity by means of the long renal catheter.

Finally, the urine may at times furnish evidence of the source of infection. The presence of renal casts is significant, and so also are crystals.

Each case, therefore, must be studied by itself. An early diagnosis of suppurative disease of the kidney is of importance, and catheterization of the ureters must be undertaken early in order to prevent the insidious process of suppuration in a kidney from advancing to such a stage that the life of the patient is endangered. It may be predicted with some confidence that in the future far advanced suppurative renal disease will cease to be met with, for these cases will be diagnosed early and nephrotomy or nephrectomy will be resorted to at a stage when this operation is attended with but little risk.

CONTAGIOUS CONJUNCTIVITIS.¹

BY MYLES STANDISH, M.D., BOSTON.

CONTAGIOUS conjunctivitis, strictly speaking, embraces all the more acute forms of conjunctivitis, but in this paper I intend to treat more particularly of the group usually spoken of as purulent or blennorrheal conjunctivitis. In this group there are four principal classes: (1) the acute catarrhal conjunctivitis, commonly called pink eye; (2) ophthalmia neonatorum; (3) gonorrheal conjunctivitis; (4) diphtheritic conjunctivitis.

Under these heads there have been grouped in the past four distinct clinical pictures, which may be briefly summarized as follows:

(1) *Acute catarrhal conjunctivitis.* A disease of the conjunctiva in which there is great congestion, some swelling of the lids, and more or less muco-purulent discharge. The cornea is rarely infiltrated and the disease runs its course in from eight days to three weeks. The eye upon recovery is unharmed.

(2) *Ophthalmia neonatorum.* A disease which appears within the first week of the child's life, being characterized by a profuse purulent or muco-purulent discharge with congestion of the conjunctiva and often very considerable edematous swelling of the lids, the cornea often becoming infiltrated, necrotic, with sloughing of the corneal tissue, leaving dense, white cicatrices,

²¹ Birsch Hirschfeld found only four cases of primary vesical tuberculosis in 2,565 autopsies in the Dresden clinic.

¹ Read before the Massachusetts Medical Society, June 8, 1897, and recommended for publication by the Society.

which make the child blind for life. That this much to be deplored result occurs only too often is demonstrated by the fact that nearly 20 per cent. of all the blind under twenty years of age become so from this cause.

(3) Gonorrheal conjunctivitis. An acute disease produced by an infection with gonorrheal pus, marked by great congestion of the conjunctiva. Edematous swelling of the lids, often very great, and characterized by a profuse flow of creamy pus, yellow without mucus, which is sufficiently liquid to flow easily down the cheek upon the opening of the lids. The cornea generally becomes seriously infected, with sloughing of the corneal tissue, and perforation as a common result.

(4) Diphtheritic conjunctivitis. An acute disease marked as the previous ones have been by great congestion of the conjunctiva, which in the course of a few days is succeeded by a deep, gray-brown infiltration, which produces in the lids a brawny, inflexible condition, so that the upper lid apparently elongates and hangs over the lower lid down upon the cheek. This brawny, brown-gray infiltration also extends onto the conjunctiva of the eye to the margin of the cornea. There is no discharge except some lachrymation in which are occasional flakes of false membrane. The cornea soon becomes necrotic, sloughs, and the eye is lost.

The above descriptions have been classical for years, but in the light of modern bacteriology must be modified very considerably, and a new nomenclature which follows the bacteriological findings must be adopted. Such a classification of purulent ophthalmias would place some cases, which from the above description would be classed as gonorrheal, under the head of diphtheritic conjunctivitis, and some cases which would formerly have been classed as acute catarrhal conjunctivitis prove to be gonorrheal, and so on. In all cases this scientific accuracy of diagnosis may not be of importance, but in others the safety of the eye depends upon an early and accurate determination of the micro-organism present. I have, with the assistance of Dr. William Daly, made an investigation of all acute cases of conjunctivitis coming on my last two services at the Massachusetts Charitable Eye and Ear Infirmary, and this paper is a summary of the result of that investigation.

The first thing to be noted is that the disease known as acute catarrhal conjunctivitis is in reality a group of a number of mild infections often produced, it is true, by a bacillus, which has been described by Dr. Weeks of New York; nevertheless, it may apparently also rise from an infection with the pneumococcus, staphylococcus, streptococcus, and perhaps by other micro organisms, not excluding an infection with gonococcus which may run so mild a course as to be mistaken for some of the other infections, although such instances are rare. A bacteriological investigation of ophthalmia neonatorum shows that almost all the cases which run a destructive course are due to an infection with gonococci, although within a few weeks I have seen a case in which a purulent conjunctivitis, originating within the first week of life, was due to an infection with Klebs-Löffler bacilli. The lighter cases of this disease have in my experience proved to be due to an infection with pneumococci. The fact that the majority of these cases are gonorrheal has made the success of the Credé method for the prevention of this disease.

In cases which present the clinical pictures of diphtheritic and gonorrheal conjunctivitis, experience has proved that bacteriological examinations are of the very greatest value, for many cases, which from the clinical pictures we have supposed to be gonorrheal, are, in reality, diphtheritic and the converse is also true to some extent, as I have seen brawny and infiltrated lids, dense infiltration of the bulbar conjunctiva with necrotic condition of the cornea and very slight, if any, purulent discharge, which upon bacteriological investigation proved to be infections from gonococci.

From the standpoint of therapeutics, it is of greatest importance that a proper bacteriological diagnosis should be made in these cases and that from this examination the line of treatment should be decided, and not from the clinical appearance of the eye. The importance of this early diagnosis is, to my mind, due to the fact that in gonorrheal ophthalmia nitrate of silver is the only application which ever controls the disease, while in diphtheritic conjunctivitis I consider that nitrate of silver hastens the destructive process which is taking place in the corneal tissue. Conversely, it is my opinion that the diphtheritic condition of the conjunctiva and consequent necrosis of the cornea will generally be controlled by prompt and persistent use of antitoxin.

After these infections of the conjunctiva, the next most dangerous form of contagious conjunctivitis is the so-called granular lids or trachoma; if this is of bacterial origin the micro-organism has not as yet been recognized, nevertheless it will spread slowly through an orphan asylum, tenement house, or any other place where the poor are crowded together, unless special means are taken to prevent this result, leaving its victims handicapped for life and often nearly blind. Fortunately it is diminishing in this country and is, compared with a few years ago, seldom seen except among recent immigrants from the eastern end of the Mediterranean, Polish and Russian Jews, Armenians and others from that locality, and I may say in passing that the presence of acute trachoma in the conjunctiva of immigrants should be a good and sufficient reason for turning them back whence they came. A large proportion of these cases within a few months after their arrival become incapacitated and are public charges. And not only this, but were it not for the new cases thus introduced into the great tenement localities of our large cities, it is my opinion that the disease would soon become extremely rare in this part of the country.

From my experience in cases of purulent conjunctivitis and trachoma, I arrive at the following conclusions:

(1) That in all cases of purulent conjunctivitis, the diagnosis should be made by the bacteriological examination and not from the clinical picture.

(2) That in the two most dangerous diseases of this class, namely, gonorrheal conjunctivitis and diphtheritic conjunctivitis, a favorable outcome of the case depends upon a correct diagnosis, as proper treatment in one disease is of no benefit in the other and may even do harm.

(3) That in cases of ophthalmia neonatorum a bacteriological diagnosis is as important as in other cases of purulent conjunctivitis, and if such were made early and prompt treatment instituted, many a child would be saved from blindness.

(4) That in every case in which a parturient woman

has a leucorrhea, if it is not convenient to bacteriologically determine the cause before the birth of the child, Credé's method should invariably be employed.

(5) Immigrants with acute trachoma should not be admitted to this country.

PURULENT OPHTHALMIA FROM THE BACTERIOLOGICAL STANDPOINT.¹

BY WILLIAM J. DALY, M.D., BOSTON.

THE importance of an early bacteriological examination in purulent conditions of the conjunctiva has already been pointed out. The clinical picture in such conditions is oftentimes, it may be said in the majority of cases, of no value in helping us to determine the etiological factor, it being absolutely impossible in some cases to distinguish clinically in the beginning between

Acute contagious conjunctivitis,

Diphtheritic conjunctivitis,

Pneumococcus conjunctivitis,

Membranous conjunctivitis, not due to the presence of the Klebs-Löffler bacillus.

Another class of purulent cases in which the differential diagnosis without microscopical examination is one of great difficulty is that offered by the infants seen for the most part in out-patient departments of large hospitals. Here is to be made a differential diagnosis between

Gonorrheal ophthalmia,

Tear sac disease from pneumococcus infection,

Acute contagious conjunctivitis (rarer).

The bacteriological examination attendant upon the successful diagnosis of these cases may be said to be divided into two parts:

(1) The examination of the smear.

(2) The examination of the growths upon culture media.

The technique of the examination is very simple and consists in the preparation of the smear in removing from the conjunctival sac a small amount of the discharge with a platinum wire which has previously been heated in the flame of an alcohol lamp or Bunsen burner, then cooled in the water of condensation of a sterilized tube, and spreading the discharge in a thin layer upon an ordinary microscope slide.

This layer is then fixed by gentle heating in the flame, and a few drops of Löffler's alkaline methylene blue poured upon the slide. It is again passed through the flame, washed off with water and dried slowly in air or by warming.

That the smear is an important step will be readily appreciated by the statement of the fact that many cases of diphtheritic conjunctivitis (and from the experience of the last year and one quarter in the laboratory of the Massachusetts Charitable Eye and Ear Infirmary during the different services, notably that of Dr. Standish, over 50 per cent., approximately estimated, of all such cases) can be diagnosed immediately, and the eighteen to twenty-four or more hours' delay attendant upon culture development obviated.

It is also possible to recognize in this manner every case of gonorrheal conjunctivitis, although in these cases a second step is essential, which consists in bleaching the micro-organism with the Gram stain, as some

intra-cellular diplococci are found resembling the gonococcus which are associated with conjunctivitis and with a marked discharge, and which on treating with the Gram stain do not bleach.

The results of repeated observations upon the characteristics of this organism warrant the statement that it is the micrococcus subflavus with which one has to do.

That the early diagnosis by means of the smear is a boon to the physician who possesses an oil immersion lens, is apparent.

The second part of the bacteriological procedure in purulent conjunctivitis consists in the examination of the growths obtained by the inoculation of the different culture media from the conjunctival sac discharge.

In the consideration of the bacteriological appearances in these conditions, it would be better to confine the description to the appearances in the smears, as the recognition of the colonies on the culture media, and the demonstration of the bacteria from the culture tubes on the slide or cover-glass, is a simpler matter than the demonstration of the organism in the smear. Incidentally it may be said that during the course of this investigation a large number of cultures were made from the conjunctival sacs of healthy individuals who exhibited no ocular trouble, and although a number of articles have been published, especially in the German journals, to the effect that all healthy conjunctival sacs contain bacteria, the experience here showed that in a large number of cases (in some series 50 per cent. or more) the tubes showed absolutely no growth, the culture media used being, for the most part, blood serum, and occasionally gelatine and agar-agar.

In the order of importance from the prognostic standpoint, diphtheritic conjunctivitis is entitled to first consideration. Proceeding as described, a piece of the membrane or a slight amount of the discharge is transferred to the slide and stained. With the aid of an oil immersion lens are made out the brightly stained nuclei of the leucocytes, the fibrine strings and meshes and clumps of conjunctival epithelium.

In the fibrin meshes and in the conjunctival cell clumps are for the most part the bacilli, lying in groups, oftentimes of eight or ten, and exhibiting the typical characteristics of club-shaped ends, and clear unstained spaces in the rod. In marked cases the membrane may be stripped off and sections made with a freezing microtome. These sections are stained with Gram's stain for bacteria in tissues, and show the bacilli lying along the edges of the membrane in large quantities.

Membrane formation of such size is, however, not the rule. The gray, thin membrane occurring in patches on the palpebral, and less often on the ocular conjunctiva, is the form of this disease that generally comes to the practitioner's notice. In such cases, if the sterilized platinum wire be rubbed along the surface of the false membrane, the typical picture may be obtained in the smear.

In this connection, it would be well to state that a small number of cases have been noticed associated with decided membrane formation, in which the staphylococcus aureus was found on repeatedly taken cultures, and which in a few days cleared up wholly and without corneal involvement.

In considering the appearances in gonorrheal ophthalmia, the smear alone is to be relied upon, as it is next to impossible and certainly impracticable to grow this

¹ Read before the Massachusetts Medical Society, June 8, 1897, and recommended for publication by the Society.

organism upon the surfaces of the ordinary culture media. A small quantity of the discharge, having been spread upon the slide, is first stained with alkaline methylene blue, and the presence of intra-cellular diplococci ascertained. Another such slide is stained with Gram's stain, which consists in first coloring with aniline oil water gentian violet, washing with water, and then treating with the iodine, potass. iodide solution of Gram, again washing with water, finally with alcohol, and drying.

Under such treatment the cells lose somewhat of their sharp outline, but the principal change is in the organism; the dark-colored diplococcus, losing its intensity, is seen as a bleached, oftentimes rose-colored, organism, within the cell outlines, and characteristically grouped. The degree of the bleaching of the gonococci is in a direct proportion to the length of time that the bleaching reagent is allowed to remain upon the slide, and may be carried so far as to render the diplococci nearly invisible. It is often possible in this manner to demonstrate the invasion of the large hexagonal and becher cells of the conjunctiva by this organism.

A specific infection of the conjunctiva by the pneumococcus sometimes followed by corneal complications seems to be, from the number of cases seen, well established. Under such circumstances the discharge is thin, and may or may not be profuse. Generally it is poor in cellular elements, and shows here and there in the smear single pneumococci. The cultures from such eyes show small pneumococcus growths.

In those forms of pneumococcus infection associated with tear duct disease in young children, both the clinical and microscopical pictures are striking. In many of these cases it is impossible to tell clinically in such children whether we have to do with a gonococcus or pneumococcus infection.

The microscopical pictures presented by smears, however, are widely different. Here the pneumococci are found in large numbers, the discharge is profuse and containing fibrin-like strings. The appearances are enhanced by a capsule stain, and exhibit a different microscopical picture from that offered by the pneumococcus infection in the adult. In the cultures, large growths of pneumococcus are formed almost to the exclusion of other organisms.

Regarding the microscopical observations in acute contagious conjunctivitis, there is at present some doubt. Dr. Weeks, of New York, claims a specific bacillus in the bacterium bearing his name. He postulates that it is to be found in every case of this disease. The experience in the bacteriological laboratory of the Massachusetts Charitable Eye and Ear Infirmary does not bear out this assumption. In some few cases the organism that he describes has been found, exhibiting upon culture media the same biological characteristics, and in the smear being identical with those in smears made by Dr. Weeks himself, and kindly lent by Dr. Standish.

The vast majority of all such cases, however, show the commoner pyogenic organisms both in the smear and growth, namely, the staphylococci, streptococci, and in some few other cases the bacillus xerosis and the bacillus pyocyaneus.

The object of this communication is principally to call attention to the fact that in those cases of contagious conjunctivitis where the clinical diagnosis in the beginning is difficult or impossible, the possessor of a

good microscope may ascertain the infection with which he has to deal, thus promoting early treatment, and using the cultures as a means of control.

Clinical Department.

A REPORT OF THREE CASES OF CANCER OF THE STOMACH IN WHICH HYDROCHLORIC ACID WAS PRESENT.¹

BY H. F. VICKERY, M.D., BOSTON.

It has been thought that the absence of hydrochloric acid in cancer of the stomach was a pretty constant symptom; and the somewhat remarkable coincidence of seeing three cases in one year all having hydrochloric acid present should be put on record. They were all three inmates of the Massachusetts General Hospital.

CASE I. Entered Dr. Shattuck's service in November, 1895. She was sixty-two years old. Digestive symptoms began about one year before entrance; in six months she had failed in weight from 160 to 97 pounds. The stomach was dilated. Vomiting was frequent, and at first there was no free hydrochloric acid found, but after she had improved somewhat it appeared. In December it is recorded that in four specimens of vomitus hydrochloric acid was present twice, and in January in nine specimens of vomitus hydrochloric acid was present five times. She improved decidedly, and was discharged much relieved in February. The great improvement, the presence of hydrochloric acid, and the absence of any tumor led to the belief that this was a case of dilatation of the stomach.

April 13, 1896, two months after she left the hospital, she re-entered, and came under my care. She had grown worse; and at this time no hydrochloric acid was obtained. A resistant mass could now be made out. She died in May.

Dr. Whitney reported: "On opening the stomach a large mass of new growth was found, extensively ulcerated, and directly continuous with a smaller mass in the liver. The growth was made up of large epithelial cells separated by a stroma of connective tissue. Diagnosis: cancer of pylorus, secondary cancer of liver, dilated stomach."

CASE II. A man, age twenty-seven, a native of Norway, and by occupation a cook, came under my care September 12, 1896. He had had some attacks of pain in the left hypochondrium as early as June, 1895, which were relieved by drinking hot water. These continued till December. Then he was free from symptoms until three and a half months before entrance to the hospital, when he had a good deal of pain, no longer relieved by hot water. At the time of entrance he had probably lost about 20 pounds; but he looked fairly well nourished, although he was pale. A tumor could be felt, which, however, was obscured when the stomach was blown up. The stomach was not dilated, and hydrochloric acid was present in the gastric juice as late as the 12th of September. The diagnosis was cancer of the posterior wall of the stomach. On the 17th of September he was transferred to the surgical side, and an exploratory incision was made; but it was evidently a cancerous growth

¹ Founded upon notes kindly furnished by Dr. J. A. Capps, Medical Internist. Read as a short communication at a meeting of the Clinical Section of the Suffolk District Medical Society, March 17, 1897.

which could not be removed. He died the 13th of October. The autopsy showed a cancer. The age of this patient is to be noted, twenty-seven.

CASE III. A man, forty-one years old, who had had digestive disturbance for about four months, with a good deal of vomiting. He was a very nervous man, and he had used at one time a great deal of tobacco. The stomach was not much dilated, holding two and one-half pints hydrochloric acid after a test-meal was present; lactic acid was absent; and the total acidity was increased, being 72 per cent., while the normal limits are 40-60 per cent. That is, this man, with what proved to be cancer, had hyperacidity; and the chances are that the acidity was mostly due to hydrochloric acid, for there was not a dilated stomach, lactic acid was absent, and fermentation did not seem to be excessive. A tumor could at times be felt; but he was very nervous, this hyperacidity was present, and he was uncomfortable on liquid food, so that I thought that possibly it might be a case of nervous dyspepsia, and I put him on full diet and doses of bromide of potash. For a time he improved very remarkably; but it was a merely temporary improvement, then he went on in the way of a cancer. Dr. Cabot attempted to prolong his life by sewing the stomach to the intestine. I think that the patient was perhaps more comfortable afterwards. He died May 11th, having been in the hospital a little over one month.

Dr. Whitney reports: "A hard, irregular, whitish mass surrounding the top of the pylorus, admitting the tip of the little finger. Primary cancer of the pylorus, secondary cancer of the liver."

ENTIRE DESTRUCTION OF SOFT PALATE AND VELUM BY SYPHILIS.¹

BY ALBERT N. BLODGETT, M.D., BOSTON.

THE patient is a boy fourteen years of age, of healthy parentage. The disease appeared three years ago, and the case was referred to me about four weeks ago, by a practitioner in another city. The following history is by a member of his family.

"He was a child of healthy parents; his father was a young man, temperate and of good habits; his mother was a young woman, had good health when the child was born, and never had humor of any kind. The child was healthy when born, and has always had the best of care and food. He never had any sickness or poor health until after being vaccinated.

"In the late fall or early winter of 1893 the city enforced the law regarding vaccination in the public schools, and all children, in order to be able to attend school, were obliged to be vaccinated if they had not been. The city sent a physician to the schools to vaccinate the children, and he was vaccinated at this time. The arm was very much swollen and very painful, and I should say he was out of school over a week. He did not seem strong after this, and in a few weeks his eyes commenced to trouble him, and grew gradually worse, until in the fall of 1894 they grew much worse, and I took him to a specialist here in the city. This doctor said it was a very bad case, and was caused by poison in the system, and gave me to understand the

poisoning was caused by the vaccination. He told me I must take the boy out of school, and that he would probably be unable to attend again for two or three years. After doctoring him for three or four weeks, the doctor said it would be a hard, long case, and advised me to take him to the Eye and Ear Infirmary in Boston. His eyes seemed to improve after taking him there. I did not take him to the Infirmary until the doctors gave up the case. He was only to go there after he had taken the medicine they gave him. His eyes seemed very much better, and his throat began to trouble him.

"A Mrs. Stasfield of this city has a little girl who was vaccinated at the same time by this doctor. This child broke out in large sores all over the body, and especially the head. These sores have been worse at times than others, and they seem to trouble her more about the time of year when she was vaccinated.

"There is another little girl in the same neighborhood by the name of Calwfrank. She had a very hard time with her arm when vaccinated, and since that time she has had a large sore on the back of her neck which has been very painful, but seems to be some better now."

No point of primary infection except the place of vaccination was at any time observed. There is a history of subsequent falling out of the hair and of an indolent long-continued inflammatory condition of the eyes, of which there is now no trace. There was at the time I saw him a place across the dorsum of the nose covered with white, glistening skin, which had attracted the attention of the mother, and was somewhat tender to the touch; a discolored patch on the upper lip was also visible. I wrote to the physician who had been attending the case, and received this note in reply.

In the case of W. F., after my examination I diagnosed it as syphilis. There was ulceration up to the posterior nares, the soft palate was almost ulcerated off so the part hung only by a few fibres. I think the cause is due to syphilitic virus [received] when he was vaccinated.

Respectfully, R. F. PEEFFERKORN, M.D.

Dr. DeBlois kindly saw the case yesterday, and diagnosticated it as one of undoubted specific disease.

The case presents very much the appearance of the colored plate marked B and the one on the succeeding page marked D, in Dr. DeBlois's article (in the "Transactions of the Laryngological Association") as far as it can be said to conform to anything I can show you.

At the time of my first examination, the boy was in bad general condition. The skin was everywhere very pale, the face haggard, pulse weak, appetite poor; and he complained of weakness and increasing languor. He has not been in school for three years, but has recently commenced a course in manual training which does not overtax his strength and which he enjoys.

Examination of body reveals enlarged glands in the right neck; none elsewhere. One large, pigmented spot is observed on the face, a few doubtful ones elsewhere. On the left arm is a large, depressed cicatrix from vaccination—thin in texture, pale in color, but not otherwise remarkable. Examination of chest negative. No history of cough. Breathing is entirely by the mouth, and the breath is of a sickening, sweetish odor and quite offensive. He cannot breathe

¹ Read as a short communication at a meeting of the Clinical Section of the Suffolk District Medical Society, March 17, 1897.

through the nose, though air can be forced through each side with some difficulty. There is an abundant, glairy, semi-purulent discharge from the nose. Speech is very defective, though the patient formerly talked well. Mouth and teeth are normal. Hard palate perfect, though the mucous membrane is somewhat thickened and injected over the posterior portion of the roof of the mouth. In the place of the velum and uvula is a yawning defect of irregular contour, with indurated and undermined margins extending entirely across the vault of the pharynx, from one anterior pillar to the other. At the outer edge of the anterior pillar of the right side is another independent, ragged, excavated ulceration, extending deeply behind the anterior pillar toward the tonsil. Another broad, superficial ulceration extends across the left anterior pillar toward the last upper molar tooth. The epiglottis and larynx are not affected.

Reports of Societies.

CLINICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

E. W. TAYLOR, M.D., SECRETARY.

REGULAR meeting Wednesday, March 17, 1897, Dr. W. F. Whitney in the chair.

DR. FRANKLIN W. WHITE read a paper on

THE DIAGNOSTIC VALUE OF TUBERCULIN.¹

DR. F. C. SHATTUCK: In my wards at the hospital this method has been practised for three years in apparently suitable cases; and during Dr. White's service, wishing to satisfy myself more fully about it, the injections were used in a wider class of cases and not simply in those in whom tuberculosis was suspected. As far as the diagnosis goes, this winter I had in almost contiguous beds in the ward pretty good illustrative cases. A woman came in with symptoms of chronic meningitis, and it was a question whether it might be specific or tuberculous. She got a prompt reaction from tuberculin which seemed to settle the diagnosis. Near her was a mulatto girl with some obscure abdominal disease — a considerable tumor, the exact relations of which were not easy to make out. She had a good deal of fever, was thin; and in view of the fever, emaciation, this rather painful lump in the abdomen and her race, there was strong reason for suspecting that she might be tubercular. After the subsidence of the fever, she failed to give any reaction, and gradually the tumor disappeared, and she went out, apparently on the road to recovery.

We have more or less trouble from the patients — I think Dr. White said 20 per cent. — who react to the tuberculin injection, but in whom we can find no other evidence of tuberculosis; and that has made me ask myself again the question I have often put to myself, namely, How many people are there who are tubercular and never know it? If one-seventh of the human race in civilized countries at all ages die from pulmonary tuberculosis alone, how many have it and get over it, and how many have it and never know anything about it? During the course of the winter a man came to the hospital to apply for admission; he soon went into convulsions and died. At the autopsy it was shown that the convulsions were due to renal

disease, and he had at the top of one lung an old tubercular focus. Suppose that man had come into the ward and we had determined his nephritis, the old tubercular focus at the top of one lung might have been entirely overlooked or given rise to no signs. Suppose he had been given a tuberculin injection and had reacted, we might have had to confess there was no evidence of tuberculosis, unless the nephritis was of tubercular nature, which it was not. I mention that, as it seems to me a matter of some importance and as helping possibly to explain the reaction in cases in which we can demonstrate no sufficient cause. I can only repeat and reinforce what Dr. White has said as to the apparent innocence of the injections. I have seen no reason to regret having used the injections in any case. The worst that happened was a transitory malaise, but never the least evidence of any acceleration of a tubercular process as a result of the injections.

DR. LIEBMANN: I would like to ask Dr. Shattuck in case there is already fever how he makes out his test then? Will there result a higher fever?

DR. SHATTUCK: We may very seldom use it in the presence of fever. Fever makes the test very uncertain.

DR. MORSE: Dr. Mason asked me to speak of a case of his at the City Hospital as showing remarkably well the action of the tuberculin test. It was a non-febrile case of the ascitic form of tubercular peritonitis in a girl of fourteen. The temperature reaction was prompt and decisive. Laparotomy was performed on the strength of this reaction. The peritoneum was studded, especially in the pelvis, with miliary tubercles. The microscopic examination of a piece of tissue removed at the operation showed typical tubercular tissue containing tubercle bacilli. This case is interesting from the very prompt reaction and the proof that the case was one of tuberculosis by the operation and the microscopical examination.

DR. STONE: Has it been the experience of others that one in five react to the test?

DR. WHITE: I found it difficult to collect any satisfactory statistics on this point, from the fact that the number of any one man's cases was usually small, and different numbers and sizes of doses were used by the various men, and the evidence for the presence or absence of tuberculosis in the cases was often incomplete.

DR. E. O. OTIS: The large number of tuberculin tests which Dr. White has reported to-night renders his paper exceedingly interesting, suggestive and valuable; and he is to be congratulated upon it. An early diagnosis of pulmonary tuberculosis is always most desirable and important; for, as we all know, it is in the early stages of the disease that treatment is most successful, and anything that can aid us in its early detection is most welcome. Brehmer long ago insisted upon the value of the spirometer as an early diagnostic sign; and more recently Kanske has elaborately developed stethometry which, as he says, "assists in the detection of incipient pulmonary disease, its indications sometimes preceding all other signs"; and now we have the tuberculin test which has revolutionized the study and management of bovine tuberculosis, and which, if we can only determine the effective minimum dose, and be assured that no evil will result, seems likely to prove a most precious early diagnostic test. Experimenters, however, do

¹ See page 123 of the Journal.

not seem to be agreed as to the safe and effective dose of tuberculin. Grasset and Wedel² from their experiments concluded that from two- to three-tenths of a milligramme for the first injection, and five-tenths for the second, was a sufficient dose for the test. Cambemale and Raviat³ thought that two deci-milligrammes were enough; while Dr. White has used with impunity considerably larger doses.

Of course, the danger to be feared in this test is the aggravation of pre-existing symptoms; and therefore the crucial question, which seems still to be doubtful, is — what is the minimum dose which is sufficient for a test, and which, at the same time will not aggravate possible existing tuberculosis. Until this is answered definitely the tuberculin test will always involve a risk. In two cases reported by Cambemale and Raviat five deci-milligrammes produced excessive reaction.

In cases of more or less advanced tuberculosis different results have been obtained by the test. Some give little or no reaction, and in others it is excessive. With cattle, according to Nocard,⁴ in very tuberculous subjects, especially in those which are feverish, the reaction may be little or nothing.

Reaction has also been obtained in some other diseases; for example, Grasset and Wedel mention a case of tertiary syphilis in which a slight reaction was obtained.

Dr. Trudeau, in the Adirondack Sanitarium at Saranac, has used the tuberculin injection as a test of recovery; if no reaction is obtained the patient is considered cured. It seems to me that many more such investigations like these of Dr. White are desirable and necessary before we can determine just what can be done with the tuberculin test with safety to the patient. Knowing its wonderful accuracy and innocuousness with cattle, it would seem that it might also become a most delicate test in the human subject, and it is to be hoped that experience may finally lead us to the safe maximum dose.

DR. WHITE: As to the question whether other disease may not give a reaction to tuberculin, I have seen this claim made in regard to syphilis, but it seems to me that the present evidence is not sufficient to prove it. In talking with the Chairman of the Cattle Commission, he stated that he thought that actinomycosis might give a reaction where there was apparently no tuberculosis in the cattle; but he had seen too few cases to feel sure of it.

DR. WHITNEY: I think any one who has done a number of autopsies will bear out what Dr. Shattuck says as to the lesions which give evidence of tuberculosis having existed at some previous time. I should like to ask Dr. White if it makes very much difference with a single dose whether it is large or small. If a patient reacts to a small dose, is the reaction greater if a large dose is given?

DR. WHITE: In our work the dose has been ten milligrammes. In treatment, doses much larger than that have been given after the first toleration is established. As to whether one dose would not be as good as another, there is no question that a dose may be too small to produce reaction; for example, in some cases where two milligrammes produced no result, a typical reaction followed ten milligrammes. There

is such a difference of opinion about the size of the best diagnostic dose that it must be a matter for further observation.

DR. STONE: As to what may be considered "healed tuberculosis," I should like to speak of a case of which Dr. Alexander Burr told me. A young cow, apparently perfectly healthy, reacted to tuberculin. On killing the animal he found, after diligent search, one small caseous gland having a thickened capsule with calcareous material in the capsule. A few giant cells proved it to be tuberculous. This is as nearly a healed condition as it is possible to imagine, certainly a very quiescent condition, and yet the animal reacted in a perfectly typical way.⁵

It is well known that a number of people in perfect health, as far as they know, have reacted to the test, and further that a large number must carry about with them quiescent tuberculous lesions. Consequently it is possible that, in addition to the admitted one in five which falsely react, there may be others who will react from the presence of these quiescent lesions when the important lesion is non-tubercular.

The varying statements in regard to the dose necessary are probably caused by the fact that tuberculin is by no means a stable product, and different lots made under apparently similar conditions have different strength, and the products of different laboratories are subject to still greater variation.

DR. ALBERT N. BLODGETT read a paper on

ENTIRE DESTRUCTION OF SOFT PALATE AND VELUM BY SYPHILIS.⁶

DR. FARLOW: This certainly seems to be a case of specific disease of the throat; and from the swelling and dusky look of the anterior pillars I should say that the disease was not yet quiescent but that further treatment was necessary.

It is not very uncommon to see such cases as the result of congenital syphilis; and, unless there is stronger proof than was given in the history as read, I should be inclined to consider it as a case of inherited syphilis.

DR. BLODGETT: My purpose in showing this case to-night is not so much on account of the pathological condition as to emphasize the importance of using bovine virus and not humanized virus which the friends of this boy think was used in this case.

DR. J. L. MORSE: I fail to see that Dr. Blodgett has shown any proof that the syphilis in this case is due to the vaccination beyond the fact that the symptoms were first noticed after the vaccination. It seems to me that the fact that the eye symptoms came on a month after the vaccination is a strong point against any causal relation between the two as the eye symptoms of syphilis are a very late manifestation. It seems to me we should make a great mistake to conclude upon the evidence given that this case of syphilis is due to vaccination.

DR. VICKERY: Inasmuch as a good many persons are unreasonably opposed to vaccination and desirous of catching hold of any argument, whether well-grounded or not, against it, I think it should be brought out clearly that so far as we have not the proof that the initial lesion was occasioned by vaccination. We have a plain case of tertiary syphilitic disease.

⁵ Dr. Burr has since told me that such occurrences are frequent, and that out of 15 cattle killed on the day of writing me three were non-tubercular.

⁶ See page 133 of the Journal.

² Bulletin Acad. de Med., 1896.

³ Bull. Méd. du Nord, September 11, 1896.

⁴ The Animal Tubercloses and their Relation to Human Tuberculosis, 1895.

but it has not been demonstrated at all how this occurred.

DR. BLODGETT: I have not intended or endeavored to prove that syphilis in this boy was due to vaccination. I have offered the history as narrated by a member of the family. I have presented the symptoms as far as they can be traced at present. My researches are not yet complete, and I exhibit the patient at this time because he lives at a distance and has at my request remained in town for that purpose. The case is one which is not especially common; and the circumstances have produced a conviction in the minds of the family that it was due to the cause assigned and to this alone. Other cases of troubles of one or another kind after the same process of vaccination in the same school by the same city official, and presumably with the same vaccine, have occurred; and the case has unfortunately attracted considerable attention in that way. I observe that no one considers the disease to be anything else than syphilis. As far as the family history goes there is no other known mode of infection than that given above. The disease is not apparently hereditary, it has never been suspected or known in any member of the family. The child's parentage is unquestionable, and I consider it possible that infection may be due to virus obtained from human sources and not from bovine sources which we should recommend for universal adoption. No more forcible argument for such adoption can be presented than the possible infection of persons vaccinated with other virus becoming thereby inoculated with any disease capable of effecting such deplorable results as are illustrated in the present case.

DR. C. W. TOWNSEND: As an example of this *post-hoc-ergo-propter-hoc* argument so often used by patients, I may mention a case very much like this that presented itself at my clinic at the Massachusetts General Hospital three days ago. There was a great deal of ulceration back of the pharynx. The soft palate and uvula had disappeared. It was a clear case of tertiary syphilitic ulceration. The patient herself said it was due to the kick of a horse when she was eleven years old. It seems to me there was as much proof of the connection with the cause as given by the patient in that case as in this.

DR. H. F. VICKERY read a paper on a report of
THREE CASES OF CANCER OF THE STOMACH IN WHICH HYDROCHLORIC ACID WAS FOUND.⁷

DR. LIEBMANN: Of late I have seen reports of several cases of cancer of the stomach where hydrochloric acid was present, especially at the first stage apparently before the glands have been destroyed, and before the atrophy of the mucosa has progressed a great way. On the other hand, I have had a case where on the base of a previous ulcer cancer sprang up and where hydrochloric acid was always to be found. Whether the hyperacidity in this case was due to hydrochloric acid I would doubt, and should think that most of the acidity was due to organic acids.

BELLEVUE HOSPITAL MEDICAL COLLEGE. — Dr. E. G. Janeway has been elected president of the faculty of Bellevue College, to fill the vacancy occasioned by the death of Dr. William T. Lusk.

AMERICAN ORTHOPEDIC ASSOCIATION.

ELEVENTH ANNUAL MEETING, WASHINGTON, D. C.,
MAY 4-6, 1897.

FIRST DAY. — TUESDAY.

DR. SAMUEL KETCH, of New York, President of the Association, delivered the Annual Address, taking for his theme

THE WORK AND INFLUENCE OF THE AMERICAN ORTHOPEDIC ASSOCIATION.

He said that just ten years ago the Association had been founded. It had been claimed that orthopedic surgery was too narrow a specialty, but this would seem to be fairly refuted by a glance at the work of the Society. Thus, 323 papers had been presented, of which 35 were on hip disease, 19 on knee-joint disease, 49 on Pott's disease, 20 on lateral curvature, 43 on club-foot and 79 on spastic paraplegia. The position of orthopedic surgery, he said, was at last an assured one; it had been forever wrested from the hands of mere instrument-makers and quacks. The address closed with several memorial sketches, including one of the venerable Dr. H. G. Davis, "the Father of American Orthopedic Surgery."

ERASION OF THE KNEE-JOINT, WITH CONSERVATION OF THE EPIPHYSEAL CARTILAGE.

DR. HARRY M. SHERMAN, of San Francisco, presented a paper on this subject. He said that if all diseased tissue could be removed without interfering with the cartilage, a certain amount of developmental energy of that cartilage might be conserved. He reported three cases in which total arthrectomy and epiphyseotomy had been performed, the epiphyseal cartilage being preserved. Although all three patients left the hospital with straight and apparently solid limbs, flexion occurred in each one in spite of the use of a plaster splint. A radiograph, which was exhibited, seemed to show that this flexion was due to the development of more bone in the anterior than in the posterior cartilage. In one of the cases, although all but a circumferential band of the epiphyseal cartilage sloughed away, this band proved sufficient to prevent further shortening. In closing, the speaker alluded to the advantages to be derived from early exploratory punctures in an effort to reach tubercular foci.

DR. CHARLES L. SCUDDER, of Boston, expressed his approval of the suggestions contained in this paper. He said that if the flexion referred to did not exceed eight or ten degrees, it would not be found objectionable, but, on the contrary, would add to the patient's comfort.

DR. R. W. LOVETT, of Boston, said that his personal experience with the conservative treatment of knee-joint disease had been fairly satisfactory, and he was rather opposed to operative measures. His experience with arthrectomy had been very discouraging. He cited a recent and seemingly desperate case, in which although he had been unable to remove all the diseased tissue at the operation, the child had been greatly improved.

DR. W. R. TOWNSEND, of New York, said that he had not found excisions in adults as satisfactory as in children, and indications were for an earlier excision.

DR. BLANCHARD, of Chicago, remarked that his experience had been just the reverse of Dr. Townsend's, having been much more favorable in adults.

⁷ See page 132 of the Journal.

The PRESIDENT, alluding to the flexion following operation, said that he had seen several cases in which the flexion had almost equalled the original deformity. He had been satisfied with the results of the conservative treatment of knee-joint in children.

DR. SHERMAN, in closing the discussion, said that as we knew now the more common situations of the early foci of joint disease, it was possible for the surgeon to do much good by exploring with a small trephine. Where he had practiced this method on the knee, it had been productive of no bad results. It was not, however, well adapted to disease of the hip-joint, owing to the deep situation of this joint.

TRAUMATIC SPONDYLITIS.

DR. ARTHUR J. GILLETTE, of St. Paul, reported three cases of traumatic spondylitis. In the first case the traumatism was quite trivial, yet this had been followed by rigidity of the spine, with pain and a slight dorsal kyphosis. The autopsy showed that the vertebræ throughout were so spongy that they could be crushed with the fingers. The iliac crest, ribs and sternum were in the same condition. The second case occurred in a man of thirty-five years, as a result of a severe sprain of the back. A post-mortem examination of the spinal column showed the spinal cord intact and the membranes softened. Both the anterior and posterior segments of the vertebræ were carious, and in the upper dorsal region was a sinus communicating with the left pleural cavity. The third patient also was a young and vigorous man, who developed the evidences of vertebral caries after some injury to the back. The autopsy showed that the spongy portions of several of the vertebræ had been reduced to a dark, pulpy mass.

SPONDYLOLISTHESIS.

DR. R. W. LOVETT, of Boston, presented a case which he thought might be fairly classified under this heading. The patient was a youth of eighteen over whose pelvis a heavy wagon had passed. Although he received no medical or surgical treatment at the time, he was soon able to go about on crutches. When first seen by Dr. Lovett last September, the shape of the hips was like that of a case of congenital dislocation of the hip, but the trochanters were on Nelaton's line. The lumbar spine appeared to project forward abnormally. A plaster-of-Paris jacket was applied under suspension, and under this treatment the patient improved rapidly. All the symptoms have now disappeared, but the deformity of the lumbar spine still persists.

DR. NEWTON M. SHAFFER, of New York, said that he had seen one case closely resembling this one so far as the condition of the spine was concerned, and another case resembling it so far as the hip was concerned. In one case there had been extreme lordosis with apparent dropping away of the spine from the sacrum. In that case the patient recovered with a position similar to that shown by the photographs of Dr. Lovett's case.

The PRESIDENT referred to a case in which, although there had been marked spinal symptoms during life, but little was found at the autopsy.

DR. WILLIAM J. TAYLOR, of Philadelphia, recalled an operation on a case of a spinal tumor, in which, although the whole of the central portion of the cord was diseased, there was no thickening of the cord itself.

TREATMENT OF TORTICOLLIS.

DR. E. G. BRACKETT, of Boston, read a paper on this subject, and reported four illustrative cases. He said that surgeons were agreed on three important points in the treatment of torticollis, namely: (1) That the contracted structures lying superficial to the deep layer of fascia must be overcome; (2) that the deeper structures—the ligaments, muscles, etc.—must be further stretched; and (3) that the muscles holding the head must be so re adapted to the new position that they will no longer tend to draw it to an abnormal position. This last part could only be accomplished by systematic massage and exercise. The patient should lie with a roll under the neck, and the head turned to the opposite side, and while in that position, deep massage should be practised on the contracted structures and on the trapezius of the opposite side. Forceful manipulations to depress the head to the point of tolerance are also requisite, and after this, with the head in as nearly the correct position as possible, the patient should be given heavy work to do with dumbbells. Dr. Brackett called attention to the fact that in one of the cases, while attempting to correct the head at the time of the operation, the patient had repeatedly developed peculiar breathing and other alarming symptoms. These symptoms had occurred in subsequent attempts at correcting the head beyond a certain point, and could be produced to a certain extent even at the present time. This rather novel complication was probably explicable on the ground that the vagus nerve had also become shortened.

DR. L. W. HUBBARD, of New York, said that he had recently treated a case of congenital torticollis occurring in a girl, twenty-eight years of age. He had operated by open incision on January 5, 1897, dividing the sterno-mastoid and trapezius and the other contracted tissues, and thoroughly stretching the parts under ether. The head was put up in plaster in an over-corrected position, and from time to time this was changed. She then wore a spinal apparatus with chin-piece for about two months, during which time she was subjected to manipulations similar to those described in the paper. This part of the treatment seemed to him of great importance.

DR. SHAFFER thought certain cases of torticollis should be relieved by systematic massage, or even by forcible intermittent traction.

DR. WILLIAM J. TAYLOR said that he had successfully made use of practically the same method of exercises as that described in the paper.

DR. BLANCHARD said that he had always found it necessary to begin with an operation.

DR. A. J. STEELE, of St. Louis, said that, after operating, he applied plaster of Paris around the head and trunk, leaving the neck free. This dressing was reinforced by two long strips of wire gauze, passing anteriorly and posteriorly, and incorporated in the plaster of Paris. Instead of the manipulations advocated in the paper, he suspended the patient by the occipito-mental strap, carrying one end of the bar far out, and the other near the centre so as to carry the head in the desired direction.

DR. LOVETT referred to two cases that he had seen in which there had been the reverse of torticollis, i.e., congenital elevation of the shoulder. When the head was put in the position of torticollis, the shoulder would come down.

DR. SHAFFER said that he had seen one case in which there had been contraction of both sternomastoid muscles, causing a forward position of the head resembling that seen in Pott's disease.

DR. BRACKETT explained that he only advocated these exercises as an adjuvant to operative measures.

SECOND DAY — WEDNESDAY.

CONGENITAL DISLOCATION OF THE SHOULDER-JOINT.

DR. CHARLES L. SCUDDER, of Boston, reported two cases of this rather rare condition. He said that in the first case, the traumatism incident to a difficult labor probably was an etiological factor; but this could not be said of the second case. The distinguishing feature between traumatic dislocation occurring at birth and true congenital dislocation of the shoulder appeared to be that in the latter there was always a lack of development of the bones of the upper extremity. The shoulder deformity was probably due to lack of development of the glenoid cavity and head of the humerus.

DR. L. W. HUBBARD said that Dr. A. M. Phelps had seen six cases, and had operated upon five of them. In four, the posterior portion of the glenoid cavity was broken off.

DR. V. P. GIBNEY, of New York, said that his experience had led him to believe that one should endeavor to secure partial ankylosis in these cases, or else perform complete resection.

DR. SCUDDER, in closing, said that the only relief to be afforded was through operative measures.

A CASE OF ASYMMETRICAL DEVELOPMENT.

DR. A. R. SHANDS, of Washington, D. C., presented a boy, now twelve years of age, in whom asymmetry had been noticed when he was but two years old. The right side was more developed than the left, and the right lower extremity was edematous and covered with numerous purplish blotches. The right thigh measured 18½ inches in circumference, and the left 13 inches. His voice was husky, but intelligence fair.

DR. A. JACOB, of New York, called attention to the asymmetry of the cranium and of the lower jaw. This was only the third case of the kind that he had ever seen. There could be no doubt, he said, that the blood-vessels on the large side were abnormal.

DR. I. ADLER, of New York, said that these cases were of interest, both from a pathological and diagnostic point of view. The condition undoubtedly arose from irregularities in development occurring early in utero-gestation. Acromegaly could be excluded from present consideration, because it never is unilateral. Elephantiasis might also be dismissed from one's mind, as in the present case there was enlargement of bone as well as hypertrophy of the soft tissues. The fact that the capillaries of the skin were abnormal was a point of much interest.

SOME EFFECTS UPON THE LEG OF PRONATION OF THE FOOT.

DR. JOHN DANE, of Boston, presented a paper on this subject, embodying the results of a special study of the mechanisms involved. He said that in pronation of the foot the greater part of the foot remains stationary, and the leg rotates upon it; also that, in addition to the generally recognized motion of the malleoli inward and slightly downward, the normal outward rotation of the tibia and fibula is replaced by an

exaggerated rotation inward. In the pronated foot the knee must be kept in constant extension by muscular force, thus causing fatigue and extreme tenderness over the inner tuberosity of the tibia. To compensate for this inverse rotation there is an exaggerated inward rotation of the fibula which, in its turn, over-stretches the internal rotators of the thigh, causing tenderness and pain in the calf and knee.

DR. LOVETT referred to the relation of the pronated foot to the back and also to beginning lateral curvature. His study of the first subject had led him to think that probably the "base position" in gymnastics was not correct, and that it should rather be a position in which the feet were kept slightly apart.

FIFTY RESECTIONS IN HIP-JOINT DISEASE.

DR. R. W. LOVETT read a paper with this title. He said that from 1878-1895, at the Children's Hospital, Boston, 1,100 cases of hip-joint disease had come under treatment, and had been treated by protection, partial fixation and traction. After the faithful use of conservative mechanical treatment, 50 came to excision. The indications for operation were: (1) Persistent deterioration of the general condition; (2) a progressive process in the joint, as shown by much induration and discharging sinuses; (3) persistent and severe pain and tenderness late in the disease, not relieved by efficient traction and fixation; and (4) the formation of extensive sequestra in the joint. In the majority of the cases, three or four years had elapsed since the time of the excision. Nineteen were known to be dead, and six others were probably dead, giving a mortality-rate of nearly 50 per cent. In about half of the cases there was ankylosis; in the others, the motion was surprisingly good.

(To be continued.)

Recent Literature.

Retinoscopy (or Shadow Test) in the Determination of Refraction at One Metre Distance, with the Plane Mirror. By JAMES THORINGTON, M.D., Adjunct Professor of Diseases of the Eye in the Philadelphia Polyclinic and College for Graduates in Medicine, etc. Twenty-four illustrations. Philadelphia: P. Blakistoun, Son & Co. 1897.

This little manual of 66 pages is certainly the clearest exposition of this method of estimating refraction of the eye that has yet been published. The methods described are not so complicated as those taught in some other hand-books.

The text is clear, and the illustrations serve the purposes for which they are designed admirably. Taken altogether, it is the most practicable hand-book on retinoscopy yet published.

Biographical Sketch of the Life and Writings of the late Professor Henry Bronson, M.D. By DR. STEPHEN C. HUBBARD. Read before the New Haven Colony Historical Society, May 27, 1895.

This appreciative biography of a physician whose life and work filled an important place in the medical history of New Haven and Connecticut during the greater part of a life which almost rounded out the century, is a handsomely printed volume of 117 pages. It gives an interesting account of the life of a man of eminence as a physician and teacher.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, AUGUST 5, 1897.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

CONCERNING HYSTERIA.

THERE is perhaps no subject in medicine about which so many hazy notions have grouped themselves as about hysteria, a disease which seems likely to enjoy its curious misnomer for many years to come. From its supposed association with the uterus it was quite natural that a popular conception should have gained ground that it was a disease peculiarly of women, an idea which is still deeply rooted, unfortunately, in the professional mind. Increasing knowledge, and the careful studies of the French school have remodelled our ideas to a marked degree, until now we clearly recognize the existence of true hysteria, not only in men, but also in children, and, rarely, even in infants. Experience has amply justified such a widening of our views; but it should also have taught us a certain conservatism in our estimate of what constitutes hysteria, in its true sense.

Hysteria and its too convenient adjective "hysterical" have served, and do still serve, as a catch-all, into which almost any doubtful morbid manifestation on the part of the nervous system may be thrown, often with an air of wisdom which is sincerely to be deprecated. Each of us has experienced this tendency, often, no doubt, with a distinct shock to his scientific sensibility. How often have we had it lightly said to us, as we have patiently and conscientiously sought for the etiology of some obscure symptom, as, for example, a sudden blindness, "Oh, that is hysterical!" and this perhaps with no further examination as to the existence of other symptoms which might in any way point to hysteria. It is invariably unfortunate and illogical to argue that because a clinical phenomenon does not conform to the symptom groups of certain well-known diseases, it must therefore by exclusion be a manifestation of hysteria.

If recent investigation on the subject has done anything, it has shown that with the broadening of our knowledge has come also a narrowing; that

whereas, on the one hand, hysteria has been shown to have a wider distribution in age and sex than was formerly supposed, it has likewise come to have a much more definite symptom-complex, and one which should not permit of its confusion with any other condition. It has assumed the dignity of a disease, in spite of its doubtful pathology, and is no longer to be regarded as a vague morbid condition, which is capable of receiving to itself the innumerable outcast symptoms which may find no other resting-place.

It would be a source of congratulation if the word "hysterical" might be absolutely abandoned; and certainly we have no further use for such hybrid terms as "hystero-epilepsy." When matters are confusing enough already, why augment our difficulties by the unscientific method of using merely descriptive terms? Because a manifestation of hysteria may simulate a so-called epileptiform convulsion, there is no adequate reason for speaking of it as an hysterical epilepsy. We must impress upon ourselves the simple fact that epilepsy is epilepsy and hysteria is hysteria, and that epileptic hysteria or hysterical epilepsy have no more scientific sense than renal pleurisy or cardiac hepatitis. There can be no question that epilepsy and hysteria are absolutely distinct conditions, small as our knowledge is of their underlying pathological anatomy. This naturally does not exclude the possibility of the two diseases being associated, in rare cases; but, even so, they are distinct one from the other.

It should, therefore, be our aim to picture hysteria to ourselves as a definite disease entity, which has a legitimate scientific claim to be regarded as such, and to avoid the popular error of confusing it with other morbid conditions, or other morbid conditions with it. If we could bring ourselves clearly to this point of view we should be much better able to direct our attention to the disease hysteria, as it occurs under unusual circumstances.

An interesting paper by Eshner, of Philadelphia, read recently before the Philadelphia County Medical Society, deals with the important matter of "Hysteria in Early Life," with a clinical report of eight cases. With one exception all of these cases occurred in children at or under fourteen. Many of them are somewhat doubtful of diagnosis, as Eshner candidly admits; but they are valuable for this very reason.

A typical case and one of much practical value is that of a school-girl of nine, who after a severe fright, occasioned by being locked alone in a room by an intoxicated father, developed a marked tremor, beginning in the right hand and arm, and extending later to the head and left arm. Following this, convulsive attacks came on, which after a few weeks averaged fifteen a day; in no one of these attacks had there been injury to the tongue. A seizure, as observed at the clinic to which the child was finally brought is described as follows:

While sitting, the child suddenly began to droop her head, then to move it forward and backward. Next, the right hand began to tremble, and then the left. Finally, the arms and legs also were set in active movement, as in the process of walking

on all fours. Frothing at the mouth occurred. The eyes were closed and the child appeared unconscious. The attack terminated in clenching of the fists and tonic rigidity of the members. The mental state following was unobscured. In the intervals between attacks there was tremor of the right hand, which ceased with the onset of the attack, and also when the child's attention was diverted or engrossed, as in conversation.

Physical examination was, in other respects, essentially negative. The child improved under suggestive treatment, and the correction of an error of refraction.

Other cases repeated in the same paper are less typical, but all certainly suspicious of hysteria.

It is well that the attention of general practitioners, as well as that of specialists, should be directed to the problems associated with the various hysterical states, and that their discrimination should be exercised in a most painstaking way to arrive at a correct diagnosis. The report of such cases as those to which we have alluded is always timely, as a stimulus to renewed care in the proper determination of the character of these most subtle of all the affections to which the nervous system is liable.

The hysteria of men is now perfectly well recognized, and conforms in a general way to the type as observed in women, nevertheless we still hear it said in professional circles that hysteria is a disease peculiarly of women, and this in spite of the manifold hysteroid affections that are continually being brought to our notice as occurring in men; for example, as the result of accidents.

We need, therefore, radicalism as well as conservatism in our views of hysteria; radicalism, as shown in a readiness to admit the possibility of its occurrence in both sexes and at any period of life; and conservatism, in demanding that the suspected symptoms shall conform to a definite disease-type.

MEDICAL NOTES.

ANONYMOUS COMMUNICATIONS.—We beg to say to correspondents who desire to discuss serious and important questions in these columns, that their names should accompany their communications, if not for publication at least as a guarantee of good faith.

CHOLERA AND PLAGUE IN BOMBAY.—Cholera is reported to have become alarmingly prevalent in Bombay of late, and bubonic plague has also broken out again.

THE FLOATING HOSPITAL OF ST. JOHN'S GUILD, NEW YORK, was struck by lightning on Friday last, and a baby was killed in its mother's arms. The same shock also caused the premature birth of another child.

THE COLOR OF SCHOOLROOM WALLS.—The New York City Board of Education are to determine what color is best to be used for the walls of schoolrooms. A commission of oculists is to be selected for the purpose. This is unquestionably a matter of considerable importance, and should receive the attention of educators everywhere.

THE PRINCE OF WALES AND THE ROYAL COLLEGE OF PHYSICIANS.—The Prince of Wales has, in the language of the *Lancet*, graciously permitted himself to be enrolled as an Honorary Fellow of the Royal College of Physicians of London.

DR. DONALD McLEAN ASSAULTED.—Dr. Donald McLean, of San Francisco, dean of the California Medical College, was shot on Friday last by a discharged employee of the college, and was dangerously wounded. His assailant killed himself when about to be apprehended by the police.

A CHAIR OF PHYSIOLOGICAL CHEMISTRY.—Upon the recommendation of the Faculty of the College of Physicians and Surgeons, Columbia University, the title of the chair of chemistry and medical jurisprudence was changed to that of physiological chemistry. The chair has not yet been filled.

BUBONIC PLAGUE AT SAN FRANCISCO.—A ship recently arrived from Calcutta is held in quarantine at San Francisco on account of the presence on board of what is supposed to be bubonic plague. One of the crew died during the voyage from Calcutta, and two of the men are ill with the same disease.

A CHEERFUL FACT FOR NEW YORK CITY.—A statistician catering for the good-will of the Greater New York says that for the six deaths every fifteen minutes there are seven births. Unfortunately, however, the births are largely from that class in the community which is of least benefit to the city.

PROFESSOR TOLDT CHOSEN RECTOR OF THE UNIVERSITY OF VIENNA.—Prof. Karl Toldt, professor of anatomy, has just been elected rector magnificus of the University of Vienna for the scholastic year 1897-98. The tenure of office is but a year, and there is usually a rotation in the selection of candidates from the different faculties that constitute the university. Professor Toldt succeeds Professor Reinisch, a jurist.

VICTORIA JUBILEE FUND.—The Victoria Diamond Jubilee Association of Chicago has raised \$7,000 to be distributed among Chicago hospitals. St. Luke's Hospital will receive \$3,000; the Presbyterian Hospital \$3,000; the Mary Thompson Hospital \$500, and the Maternity Hospital \$500. The Association asks that the hospitals name the bed, room or ward thus established in honor of Queen Victoria.

APPARENT DEATH.—A Committee has been formed in Naples for the study of the question of apparent death. The President is Dr. Oscar Giacchi, and the members are Drs. G. Albertolli, F. Bonelli, E. Chiaisio, S. Lauza, F. Conti, L. Lombar, and P. Vandoni, and Miss Elizabeth Berkeley-Barter. The Secretaries of the Committee are Dr. F. Bonelli and Signor C. Gallo. It is hardly to be expected, however, that the committee will throw any new light on the question.

NEW WAY OF RIPENING FRUITS.—"The next time you buy any fruit from a street peddler," said Dr. Constantine of the Health Department, "it might be well to remember that it was probably ripened in some filthy tenement-house bed. It is a common prac-

tice for Italian fruit vendors," he continued, "to hasten the ripening of bananas, oranges and lemons by placing them in their beds, where the fruit receives the animal heat from their bodies. Fruit subjected to this process will ripen in an incredibly short time."—*Buffalo News*.

SURGICAL AMENITIES SIXTY YEARS AGO.—In comparing the standards of professional courtesy at the dawn of the Victorian era with those of the present day, the *Practitioner* remarks, we hope with truth, that "it would be impossible at the present day for a hospital surgeon to exhibit the skull of an ape in the operating theatre with the object of suggesting a resemblance between the cranial conformation of the animal and that of a colleague, as Liston is said to have done behind the back of Syme when he was lecturing."

A PRIZE FOR THE DISCOVERY OF THE BACILLUS OF YELLOW FEVER.—A bill has been introduced into the Legislature of Brazil offering a prize of \$220,000 to be divided into two equal parts, which are to be awarded to the author of a work demonstrating the existence of a bacillus of yellow fever, and the method of recognizing it, and to the discoverer of an effective treatment of the disease. The Medical Institute of Rio Janeiro, the Hygienic Institute of Berlin, and the Pasteur Institute of Paris are to decide upon the award. The bill further provides for the reservation of a sum of \$110,000 to found an establishment for the preparation of a curative serum, the discoverer of which shall be appointed organizing director of the institute. The first of these prizes will probably be awarded to Dr. Sanarelli, an account of whose work was given in our issues of July 22d and 29th.

MEDICAL SCHOOLS IN DENVER.—As reported in the last issue of the *JOURNAL*, the Supreme Court of the State of Colorado has forbidden the University of Colorado from carrying on any part of its Medical Department in Denver because the Constitution locates the University itself at Boulder. In consequence of this, the members of the Faculty resident in Denver have resigned, and the larger portion of them have united with the Medical Department of the University of Denver. Among those who have thus strengthened the Denver Medical School are: Dr. H. T. Pershing, in Diseases of the Mind and Nervous System; Drs. S. G. Bonney and H. B. Whitney, in Medicine; Dr. Charles A. Powers, in Surgery; Dr. Walter A. Jayne, in Gynecology; Dr. George B. Packard, in Orthopedics; Drs. L. E. Lemen and J. W. O'Connor, in Clinical Surgery; Dr. T. E. Taylor, in Clinical Obstetrics; and Dr. John Chase, in Clinical Ophthalmology. The Faculty of the School has been further enlarged by the election of Dr. P. V. Carlin, in Obstetrics; Drs. W. H. Bergtold and W. B. Fenn, in Pathology; and Dr. Carroll E. Edson, in Therapeutics.

OUGHT PHYSICIANS TO WRITE POETRY?—A volume of Dr. Frederick Petersen's poems was recently produced in a court-room where he was giving

expert testimony in a murder trial, presumably in order to detract from the value of his testimony. *Leslie's Weekly* makes the following comment: "Whenever a medical man writes poetry it is viewed with some suspicion; the example of Dr. Oliver Wendell Holmes to the contrary, notwithstanding. But Dr. Petersen, like Dr. Weir Mitchell, has wooed the muse to some purpose, and his verses are distinctly good. The volume in question was the second he has produced, each of them containing a number of charming lyrics and some clever translations from the Swedish. The author is about thirty-six years old, and already a distinguished alienist. His volume of verses, 'In the Shade of Ygdresil,' was published by the Putnams."

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, August 4, 1897, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 27, scarlet fever 12, measles 11, typhoid fever 8.

BOSTON MEDICAL LIBRARY.—One of the leading physicians of Boston, in making his will, has left a large sum of money for the benefit of the Boston Medical Library. We trust that there are others.

MEDICAL REGISTRATION IN NEW HAMPSHIRE.—It is reported that physicians are registering in New Hampshire under the new law at the rate of twenty-five to thirty a day. The first examinations are now being held in the senate chamber at Concord, under the direction of Regent Gowing.

NEW YORK.

THE NEEDS OF THE INFANT ASYLUM ON RANDALL'S ISLAND.—The application of the Charities Department recently, during the absence of Mayor Strong, for \$5,600 for a new cow stable for the Infant Asylum on Randall's Island led Acting Mayor Jeroloman to make an investigation of the affairs of that institution, which revealed the fact that, notwithstanding the efforts of the present Commissioners of Charities, the mortality among the infants there still reaches the enormous rate of nearly 90 per cent. In April last, when the Commissioners were first able to successfully resist political control of the hospital, they received a communication from members of the Medical Board in which the following warning was given: "The Infants' Hospital on Randall's Island is almost certain death to every child who enters it under six months of age. This statement is absolutely true, and its truth is well known to every one who has been connected with the institution, as well as to yourselves; and, while not expecting you to perform the impossible, if some measures are not undertaken, we shall be forced to the conclusion that you are indifferent to this legalized infanticide." This communication naturally shocked the Commissioners, and since then they have done what was in their power to reform existing abuses; but much still remains to be accomplished

before the infants are properly cared for. The sanitary conditions of the hospital are bad, the supply of good milk inadequate, and the number of nurses insufficient for the duty required of them. On his return to the city the first of August, Mayor Strong expressed himself as deeply interested in the matter, and promised to confer immediately with the Commissioners of Charities in regard to improving the condition of affairs. It may be stated that as a result of the present investigation, the Board of Apportionment at once passed the appropriation for the new cow stable, and on learning of it the President of the Board of Charities made the following statement: "Before next November we expect to have under full operation what you might call a model sanitary dairy. More than thirty cows will be housed in one of the finest barns in New York State. Close by will be a building of cement and iron, where the vessels will be chemically cleansed, and where a strict record will be kept of the amount and kind of milk given every day to each baby."

DEATH OF DR. JOHN J. H. LOVE. — Dr. John J. H. Love, of Montclair, N. J., died suddenly of cardiac disease on July 20th. He had been called in consultation by Dr. Levi W. Case in a case in which an operation was necessary. The operation was performed, and Dr. Love was cleaning his instruments, when he fell to the floor, and was dead before Dr. Case could reach him. Dr. Love was born in Warren County in April, 1833, and was graduated from Lafayette College, at Easton, Pa. In 1855 he was graduated from the Medical Department of the University of the City of New York, and commenced the practice of his profession at West Bloomfield, now Montclair. In 1862 he entered the medical service of the United States Army, and in 1863 was a brigade surgeon-in-chief in the Army of the Potomac. He resigned his commission in 1864 and resumed his private practice. He leaves a widow, two daughters and a son.

Miscellaneous.

KOCH'S NEW TUBERCULIN IN LUPUS.

REPORTS are rapidly coming in of the effect in various tubercular affections of Koch's new tuberculin. As was to be expected, there is a certain amount of disagreement among observers; it is, however, a source of congratulation that the over-enthusiasm of a few years ago is in absolutely no danger of repetition.

The peripheral manifestations of tuberculosis are especially valuable as a means of study, on account of the ease with which any change for better or worse may be at once noted. Although too soon to state anything definite as to final results, certain interesting reports regarding lupus, as treated by tuberculin, have already been made public.

It is reported in the *British Medical Journal* for July 17th, that at the meeting of the Dermatological Society of London on July 14th, Mr. Malcolm

Morris showed a series of cases of lupus treated during the last few months by repeated injections of Professor Koch's "new tuberculin." "In two at least of the cases the effect of the treatment on the disease has been very remarkable, and in all it has been encouraging. Lupus of the face of the most virulent kind, which could not be controlled by any treatment, has been altogether altered in character, and has not only ceased to spread, but has begun to heal at various points, which are now occupied by white, soft scars. The effect is most marked in the cases with much 'apple-jelly' material, and little scarring due to previous applications. It remains to be seen how far this curative effect of the new tuberculin will go, and whether the disease process will be merely held in abeyance for a time, or permanently suppressed. The hope is that the course of injections when completed will produce a condition of immunity to the bacillus tuberculosis, and that the whole process in the skin will then cease. The new tuberculin produces in moderate doses a general reaction, which is sharp but short. This reaction is an objection to the treatment which patients suffering from this disfiguring disease do not make much of. A difficulty which is likely to stand more seriously in the way of a general use of the new preparation is its cost, which is very high and apparently out of proportion to the cost of production. Mr. Morris stated that with some of his cases he had already reached doses which cost eight shillings and sixpence for each injection, and before the case is finished and immunity produced, doses probably twice as large will be required. At the present time, also, there seems to be some difficulty in obtaining a sufficient supply."

Professor Lassar, of Berlin, has also made use of tuberculin in a number of lupus cases, and thinks well of it as a means of treatment, while clearly recognizing the fact that any definite statements as to its efficiency would be premature. He has seen, as yet, no cure, but enough improvement to encourage him in its further use. He also bewails the expense of the product. It is to be hoped that this objection, which now stands so much in the way of adequate experimentation, may soon be removed.

KOCH'S NEW TUBERCULIN.

AN esteemed Chicago correspondent writes to the *New York Medical Journal* as follows:

"The results of the experience of L. von Neuenki, Maczewski, and Loguecki with this newest discovery of Koch's, published in the *Presse médicale*, No. 46, do not throw a very favorable light on the purity of the preparation, which, as such, in the opinion of Koch, cannot be improved upon. The method of preparation, as lately published by Koch, gave reason to suspect that during the process a contamination with other bacteria might occur. Neuenki injected a tuberculous patient with the tuberculin and observed after every injection a decided general reaction with chills and fever. On examination, he found that the tuberculin contained numerous pneumococci, staphylococci, and streptococci, which grew well on nutrient media, thus showing evidence of undisturbed vitality. The same result was obtained from two other phials, which were opened aseptically. The authors believe that such contamination of the tuberculin is able to

produce consequences disagreeable for the patients treated, and think it necessary that the manufacturers should furnish the public with a sufficient guarantee of the absolute purity of the tuberculin by reliable tests of their products."

ANOTHER APPLICATION OF X-RAYS.

THERE is apparently no limit to the possibilities of the new photography in disclosing inner portions of the animal body. The following ingenious application of the rays to the study of the arteries, to which the *Medical Record* draws attention, may well be of considerable value in anatomical study.

At a recent meeting of the Pathological Society of Manchester, Dr. Raw explained to the society a method he had adopted for skiagraphing the arteries. He said that, when trying to examine a fracture which was enveloped in a thin layer of plaster of Paris, he found it quite opaque to x-rays. The idea then occurred to him that the vessels (arteries) might be reproduced in the skiagraph by injecting them with a somewhat similar substance. Accordingly, when the next opportunity occurred, he injected post mortem a solution of calcium sulphate and carmine into the femoral artery and then took skiagraphs of different parts of the body. He illustrated his remarks by exhibiting several pictures showing the arteries perfectly, even to the most minute anastomoses. In fact, so opaque was the substance that the arteries actually showed through the bones. Dr. Raw also exhibited a twenty-four by eighteen inch bromide print of a child, showing all the arteries of the body injected.

Correspondence.

SOLD ONLY BY SUBSCRIPTION.

PORTLAND, ME., July 28, 1897.

MR. EDITOR:—How long are the subscription-book people to abuse our patience? I don't know who the particular Catiline is, to whom my Ciceronian invective applies; I only know that he controls the sale of medical books which I have been unable to buy.

About three weeks ago I sent to a firm of booksellers in Portland an order for medical books, all of which were delivered to me within three days, except one—a book which is "sold only by subscription." Accordingly, I wrote to the publishers, asking how I could procure a copy. Here are the exact words of the reply, received to-day:

NEW YORK, July 27th.

DEAR SIR:—Your favor of the 10th inst. has been received. In reply to your inquiry we beg to say that a copy of _____ can be promptly obtained on application to us.

Those sixteen days of metropolitan promptitude are duly admired down here in the sleepy East, but pray advise me, Mr. Editor, how I am to get my book. Must I wait eighteen more days, unless in the mean time I am vouchsafed a visit from the voluble agent in whose baronial territory I am serf?

Last year I tried to get a new edition of another "subscription" book, published by the same enterprising firm, and succeeded only when I discovered who the local agent was. But this year there is a different agent, and the publishers do not even disclose his name and address. It is easier to buy a house than a subscription medical book—except at times selected by the agent, at the inconvenience of the purchaser.

How long, Mr. Editor, must we poor worms be ground beneath the heel of tyranny, before we turn?

Very respectfully yours,

ADDISON S. THAYER, M.D.

METEOROLOGICAL RECORD

For the week ending July 24th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Date.	Barometer	Thermometer.		Relative humidity.		Direction of wind.		Velocity of wind.		We'ather.		Rainfall in inches.

Amesbury	10,920	—	—	—	—	—	—	—	

Deaths reported 3,719; under five years of age 1,970; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping-cough, erysipelas, and fever) 1,140, diarrheal diseases 957, consumption 289, acute lung diseases 174, diphtheria and croup 74, typhoid fever 33, whooping-cough 24, scarlet fever 22, cerebro-spinal meningitis 16, measles 11, erysipelas 1, small-pox 1.

From whooping-cough New York 8, Philadelphia 5, Chicago 4, Baltimore and Boston 2 each, Brooklyn, St. Louis and Cleveland 1 each. From scarlet fever Philadelphia 7, New York 6, Brooklyn 4, Boston, Cincinnati, Cleveland, Lynn and New Bedford 1 each. From cerebro-spinal meningitis New York and Worcester 4 each, Philadelphia and Brooklyn 2 each, Baltimore, Boston,

Cleveland and Malden 1 each. From measles New York 5, Cleveland 2, Chicago, Philadelphia, Brooklyn and Haverhill 1 each. From erysipelas New York 1. From small-pox New York 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,992,524, for the week ending July 17th, the death-rate was 16.6. Deaths reported 3,501; diarrhea 244, measles 147, whooping-cough 73, diphtheria 52, scarlet fever 32, fever 23.

The death-rates ranged from 11.2 in Croydon to 32.2 in Preston; Birmingham 16.2, Bradford 15.6, Gateshead 13.4, Hull 14.1, Leeds 13.0, Leicester 15.9, Liverpool 19.3, London 16.3, Manchester 20.8, Newcastle-on-Tyne 18.2, Nottingham 15.9, Sheffield 18.4, West Ham 14.1.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 24, 1897, TO JULY 30, 1897.

Leave of absence for four months, to take effect upon the arrival of CAPTAIN FRANK R. KEEFER, assistant surgeon, at Fort Walla Walla, Wash., is granted CAPTAIN JOHN L. PHILLIPS, assistant surgeon.

Leave of absence for one month, with permission to apply for an extension of one month, is granted COLONEL DALLAS BACHS, assistant surgeon-general, U. S. Army, Omaha, Neb.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JULY 24, 1897.

L. W. SPATLING, passed assistant surgeon, detached from Naval Hospital, Norfolk, and ordered to Naval Hospital, Philadelphia, July 19th.

R. M. KENNEDY, passed assistant surgeon, detached from Naval Hospital, Philadelphia, July 19th, and ordered to Naval Hospital, Norfolk.

J. C. PRYOR, assistant surgeon, detached from Naval Laboratory, New York, and ordered to the Naval Hospital, Mare Island, Cal.

W. M. WHEELER, assistant surgeon, detached from Naval Hospital, Mare Island, and ordered to the "Oregon."

A. FAKENHOLT, assistant surgeon, detached from the "Oregon" with insane patient to Washington, then to the "Vermont."

C. E. RIGGS, assistant surgeon, detached from the "Vermont," and ordered to the New York Navy Yard.

A. F. PINCE, medical inspector, detached from the New York Navy Yard, July 14th, and ordered to the "Olympia" as fleet surgeon.

J. A. HAWKE, medical inspector, ordered to the New York Navy Yard, August 14th.

J. G. AYERS, medical inspector, detached from the "Olympia" as fleet surgeon, ordered home and granted two months' leave.

H. E. AMES, surgeon, detached from the "Cincinnati," July 25th, and ordered to the Naval Hospital, Yokohama, per steamer, August 14th.

J. C. BARNES, surgeon, detached from the Norfolk Navy Yard and ordered to the "Cincinnati," July 25th.

P. FITZSIMONS, surgeon, detached from Naval Hospital, Yokohama, on relief, ordered home and placed on waiting orders.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE TWO WEEKS ENDING JULY 24, 1897.

NORMAN, SEATON, assistant surgeon. To proceed to Memphis, Tenn., and assume temporary command of service for thirty days and then to rejoin station. July 20, 1897.

BOOKS AND PAMPHLETS RECEIVED.

Niagara University, Medical Department, Fifteenth Annual Announcement, 1897-98.

Sixteenth Report of the State Board of Health of Wisconsin, 1895-96. Madison. 1897.

The Value of the Chrome-water Treatment in a Case of Syphilis Maligra. By Dr. J. Edmund Guntz, Dresden. 1896.

Urinalysis, a Guide for the Busy Practitioner. By Heinrich Stern, Ph.D., M.D. New York: E. R. Pelton. 1897.

Tenth Annual Report of the Board of Health of the City of Newport, R. I., for the year 1896, with Mortuary Statistics. 1897.

Should we Treat Pulmonary Tuberculosis as a Contagious or as a Communicable Disease? By S. A. Knopf, M.D. Reprint. 1896.

The Woman's Medical College of the New York Infirmary for Women and Children, Annual Catalogue and Announcement, June, 1897.

Ventral Hernia Resulting after Abdominal Section and its Treatment. By Andrew F. Currier, M.D., of New York. Reprint. 1897.

Sixteenth Annual Announcement of the New York Post-Graduate Medical School and Hospital, University of the State of New York for 1897-98.

A Contribution to the History of Leprosy in Australia. By J. Ashburton Thompson, M.D., D.P.H. London: Macmillan & Co., Covent Garden. 1897.

Gonorrheal Endocarditis. Arsenical Neuritis, with the Report of a Case occurring in a Lad of Five Years. By Alfred Steugel, M.D., Philadelphia. Reprints. 1897.

Syphilis in Nase, Rachen, Ohr und Auge, und die Behandlung derselben, insbesondere die Chromwassercur. Von Dr. F. Bloebaum in Köln. Leipzig, Berlin, 1897.

Second Annual Report of the Institutions Commissioner with Fifty-eighth Annual Report of the Insane Hospital of the City of Boston for the year ending January 31, 1897.

Transactions of the American Pediatric Society, Eighth Session, held in Montreal, Can., May 25, 26 and 27, 1896. Edited by Floyd M. Crandall, M.D. Volume VIII. 1896.

The Eye as an Aid in General Diagnosis. A Hand-Book for the Use of Students and General Practitioners. By E. H. Linnell, M.D. Philadelphia: The Edwards & Docker Co. 1897.

The Position or Posture of the Patient during Parturition, with Special Reference to the Merits of the Walcher Position. By Andrew F. Currier, M.D., of New York City. Reprint. 1896.

The Pocket Therapist, a Concise Manual of Modern Treatment for Students and Junior Practitioners. By Thos. Stretch Dowsie, M.D., F.R.C. Edin., etc. Bristol: John Wright & Co. 1897.

A Course of Practical Histology. By Edward Albert Schäfer, LL.D., F.R.S., Jodrell Professor of Physiology in University College, London. Second edition. Philadelphia: Lea Brothers & Co. 1897.

Reference-Book of Practical Therapeutics by various authors. Edited by Frank P. Foster, M.D., Editor of the *New York Medical Journal*, and of Foster's Encyclopedic Medical Dictionary. In two volumes. Vol. I. New York: D. Appleton & Co. 1896.

The American Text Book of Operative Dentistry. Edited by Edward S. Kirk, D.D.S., Professor of Clinical Dentistry in the University of Pennsylvania, Philadelphia, etc. Illustrated with 751 engravings. Philadelphia and New York: Lea Brothers & Co. 1897.

Twenty-ninth Annual Report relating to the Registry and Return of Births, Marriages and Deaths in Michigan for the year 1895. By the Secretary of State of the State of Michigan. Edited by Cressy L. Wilbur, M.D., Chief of the Division of Vital Statistics. Lansing, Mich.: By Authority. 1897.

System of Diseases of the Eye. By American, British, Dutch, French, German and Spanish authors. Edited by William F. Norris, A.M., M.D., and Charles A. Oliver, A.M., M.D., of Philadelphia, Pa., U. S. A. Vol. II. Examination of the Eye, School Hygiene, Statistics of Blindness and Antisepsis. Philadelphia: J. B. Lippincott Co. 1897.

A Short Practice of Midwifery, embodying the Treatment adopted at the Rotunda Hospital, Dublin. By Henry Jellet, B.A., M.D., B.Ch., B.A.O. (Dublin University), L.R.C.P.T.L.M.; Assistant Master, Rotunda Hospital. With a preface by W. J. Smyly, M.D., F.R.C.P.T., Late Master of the Rotunda Hospital. With 45 illustrations and an appendix containing the statistics of the hospital for the last seven years. Philadelphia: P. Blakiston, Son & Co. 1897.

A System of Practical Medicine. By American authors. Edited by Alfred Lee Loomis, M.D., Late Professor of Pathology and Practical Medicine in the New York University, and William Gilman Thompson, M.D., Professor of Materia Medica, Therapeutics and Clinical Medicine in the New York University. Vol. II. Diseases of the Digestive System, of the Liver, Spleen, Pancreas and other glands. Gout, Rheumatism, Diabetes and other Constitutional Diseases. Illustrated. New York and Philadelphia: Lea Brothers & Co. 1897.

Eye-Strain in Health and Disease, with Special Reference to the Amelioration or Cure of Chronic Nervous Derangements without the Use of Drugs. By Ambrose L. Ranney, A.M., M.D., Author of "Lectures on Nervous Diseases," "The Applied Anatomy of the Nervous System," "A Treatise on Surgical Diagnosis," "Practical Medical Anatomy," etc., late Professor of the Anatomy of the Nervous System in the New York Post-Graduate Medical School and Hospital, etc. Illustrated with thirty-eight wood engravings. Philadelphia, New York and Chicago: The F. A. Davis Co. 1897.

Original Articles.

SOME OF THE GENERAL PRINCIPLES WHICH SHOULD GOVERN OPERATIONS FOR OTITIC BRAIN DISEASE.¹

BY J. ORNE GREEN, M. D., BOSTON.

THE otitic brain diseases are four:

- Pachymeningitis externa with extra-dural abscess,
- Leptomeningitis or arachnitis,
- Encephalitis or brain-abscess,
- Phlebitis and thrombosis of the sinuses and jugular vein;

all caused by infections from the ear, the microbes being the same varieties as are found in the suppurating ear-cavities, chiefly streptococci, staphylococci and pneumococci.

The proportion of deaths from otitic brain disease to deaths from all other causes and to the total number of inhabitants is given in Table I, taken from Körner.²

TABLE I.
PRUSSIAN STATISTICS FOR 1885.
FREQUENCY OF DEATHS FROM OTITIC BRAIN DISEASE.

Age.	Total Inhabitants.	Total Deaths.	Total.	In 10,000 living.	Per cent. of all deaths.
0-10	7,110,695	371,323	811	1.14	0.22
10-20	5,726,644	26,130	1,346	2.35	5.15
20-30	4,625,908	33,516	1,291	2.79	3.85
30-40	3,596,465	38,269	553	1.53	1.44
Above 40	7,456,231	247,621	536	0.72	0.21
Unknown	2,527
	28,518,470	716,859	4,537	0.63%

The relative proportion of the different otitic diseases is shown in Table II.

TABLE II. COMPARISON OF OTITIC BRAIN DISEASES.				
Sinus-phlebitis and pyemia	Körner	41	Pitt	22 63
Brain abscess	"	43	"	18 61
Meningitis	"	31	"	15 46
		115		55 170

The proportion of otitic to other meningitides is shown in Table III.

TABLE III. MENINGITIS.		
In 9,000 Autopsies:		
Otitic meningitis	15	= 0.16%
Tubercular meningitis	162	= 1.8%
Meningitis from other causes	133	= 1.48%
	310	= 3.44%

About five per cent. of all meningitides are otitic (Pitt).

The causes of brain abscess are given in Table IV.

TABLE IV. BRAIN-ABSCESS.		
In 9,000 autopsies, 56 cases, produced by		
Diseases of ear and temporal bone	18	= 0.2%
Diseases of other cranial bones	8	
Trauma	9	
Pyemia	9	
Lung disease	8	
Unknown	4	
	56	= 0.62%

About one-third of all brain abscesses are of otitic origin (Pitt).

The causes of sinus-phlebitis are given in Table V.

TABLE V. SINUS-PHLEBITIS AND THROMBOSIS.		
In 9,000 autopsies, 44 cases, produced by		
Disease of ear and temporal bone	22	= 0.24%
Other suppurations near sinus, tumors,		
pyemia	4*	
Carbuncle	5	
Trauma	7	
Debilitating diseases	8*	
	44	= 0.48%

* Ten of these simple thrombosis without phlebitis.

Two-thirds of all sinus-phlebitides due to disease of ear and temporal bone (Pitt).

After these tables I would call attention to Table VI.

TABLE VI. DEATHS FROM SUPPURATION OF THE EAR.			
In 9,000 Autopsies	57 = 0.6%	= 1-158.	Pitt, Guy's Hospital.
In 8,028 Autopsies	45 = 0.56%	= 1-178.	Three London hospitals.
17,028	102	0.6%	= 1-167.
In 33,017 Ear Patients	164 = 0.3%		Gürekner.
In 5,000 Ear Patients	15 = 0.3%		Randall.
38,017	119	0.3%	
In 325 Tympanic Suppurations	4 = 1.2%		Bezold.
In 1,137 Tympanic Suppurations	10 = 0.88%		Chauvel.
In 8,425 Tympanic Suppurations	35 = 0.4%		Schwartz.
In 820 Tympanic Suppurations	20 = 2.4%		Barker.
10,707	69 = 0.64%		Körner.

With all of the otitic brain diseases, except arachnitis, aseptic surgery has dealt successfully.

Statistics of operations for sinus-phlebitis, Table VII.

TABLE VII. OPERATIONS ON LATERAL SINUS.			
	Cured.	Died.	Total.
With ligation of jugular	26 = 63.4%	15 = 36.6%	41
Without ligation of jugular	16 = 42%	22 = 58%	38
	42	37	79
Ligation before evacuation of sinus.	19 = 48%	9 = 22%	28
Ligation after evacuation of sinus	6 = 0%	4 = 10%	10
Ligation without evacuation of sinus	1 = 2%	1 = 5%	2
Ligation between beginning and end of sinus	0	1	1

Cause of death in the above thirty-seven cases:

Pyemia with lung abscesses	12
Pyemia without lung abscesses	5
Leptomeningitis	11
Leptomeningitis and pyemia	3
Brain abscess	2
Shock	1
Not determined	3
	37

Statistics of operations for brain-abscess, Table VIII.

TABLE VIII. OPERATIONS ON BRAIN ABSCESSES.			
	Cured.	Died.	Total.
Cerebrum	42 = 55.3%	34 = 44.7%	76
Cerebellum	9 = 56.25%	7 = 43.75%	16
	51	41	92

In these 92 cases, multiple abscesses in 8 = 8.7% (Körner).

Certainly this is a very favorable showing for diseases in which the prognosis is desperately bad without surgical interference, and in which medicine is absolutely powerless; but these statistics must not be regarded as showing the actual proportion of cures and deaths, for many cases of operation, especially the unsuccessful ones, are never reported. A careful study of the individual reports does, however, show recoveries in apparently the most desperate cases of all of the diseases, except arachnitis, which is universally regarded as beyond surgical relief. It also shows that the earlier the operation is done the more likely success will result.

¹ Read before the Massachusetts Medical Society, June 8, 1897, and recommended for publication by the Society.

² Die Otischen Erkrankungen des Hirns, der Hirnhäute und der Blutleiter.

This brings up directly the question of diagnosis, both pathological and localizing. In none of these brain diseases is there any one or any combination of characteristic symptoms which enables us to make a positive pathological diagnosis in every case. Almost all symptoms are occasionally seen in two or more of the diseases, and in a large proportion of cases the full complex of symptoms which makes up the clinical picture and enables us to give a reasonably positive diagnosis only appears a few hours before death, when the vital forces are too exhausted to justify surgical interference. Positive localizing symptoms are in a very large proportion of the cases absolutely wanting throughout the disease, for the portions of the brain in direct relation to the ear, those parts where the otitic brain disease occurs in almost all cases, contain no centres for mobility or sensibility, and only the centres for amnesic aphasia and perhaps the centre for hearing in the opposite side; while the only cerebral nerves likely to be involved early are the seventh (facial), and eighth (auditory), and an affection of these nerves occurs so often from the tympanic disease that they are of no value for cerebral localization.

I would not be understood as undervaluing the very accurate description of the clinical symptoms of these diseases which we possess in some of our recent works, nor the wonderful progress which has been made in cerebral localization; but I do believe clinical experience already teaches that if we wait for a complete pathological and localizing diagnosis, many cases will be lost which might have been saved if justification had been found for an early operation. Are we then justified in operating on a suspected diagnosis merely?

The otitic brain diseases are usually due to the suppurative of the ear cavities affecting the bone which lies against the dura.

TABLE IX.
DISEASE OF THE BONE. KÖRNER.

		Bone diseased to dura.	Diseased but not to dura.	Bone healthy.
Sinus diseases .	39	32 = 82%	3 = 7.7%	5 = 12.3%
Brain abscesses .	40	37 = 92%	1 = 2.5%	2 = 5.5%
Meningitides .	30	17 = 57%	4 = 13.3%	9 = 30%
	109	86 = 78%	8 = 7.3%	15 = 13.7%

The recognition of this fact, that the bone is diseased directly to the dura in 79 percent. of the cases of otitic brain disease, constitutes one of the most important advances of our knowledge within the last few years. It gives us justification for early exploration of the bone, and as disease of the bone originates from suppurative of the ear, the ear is the cavity from which the bone should be explored, if this is possible, that is, we should follow the disease inwards from its source.

The frequency with which the dura is exposed in mastoid operations and found healthy, although lying in direct contact with diseased bone, shows that it is a membrane not easily infected; on the other hand, mastoid operations, with removal of all carious bone, not infrequently lead one into the cranium and reveal extensive pachymeningitis which had given no symptoms, or show phlebitis and thrombosis of the lateral sinus which had also given no symptoms because the thrombus had not yet broken down and infected the general system. Clinically it often happens that with a suppurating ear we have symptoms which we are confident are to be referred to the brain, and yet with the most careful study are unable to say whether the disease is in the cerebrum or in the cerebellum, whether it is

pachymeningitis, phlebitis or brain abscess. By exploration of the bone these doubts can be solved, and we are in position to immediately and early treat the brain disease, and also remove the diseased bone which, if left, is liable to re-infect the brain tissues. Given a suppurative of the ear with symptoms, however slight, pointing to the brain, open the ear-cavities and explore the bone. This can be done in most cases by a tympano-mastoid exenteration which exposes the entire roof of the tympanum, aditus and antrum, and also the inner wall of the mastoid; but in exceptional cases this operation is impossible, owing to osteo-sclerosis of the mastoid, to the tympanic roof lying very low, or to unusual projection outwards of the sigmoid groove. In these exceptional cases the bone must be exposed directly; the tympanic roof by entering above the linea temporalis, the inner mastoid wall by removing the mastoid. In the twenty-one per cent. of cases in which the bone is not diseased up to the dura the same rules for operating are applicable, for the chances are still that the brain disease is in close proximity to the temporal bone. The only exceptions are the very rare cases of abscesses in the first (upper) convolution of the temporal lobe, or the still rarer cases of abscesses in the frontal or parietal lobes which require operation directly over their situation; and for the recognition of this situation we must depend upon the whole complex of symptoms and the established rules of localization.

To summarize what I have endeavored to express briefly and without elaboration on account of the short time allowed:

(1) In otitic brain disease early operation is advisable, but an early exact diagnosis is often impossible.

(2) The chances are 79 in 100 that a fistula through the bone from the ear will lead directly to the brain disease.

(3) The infected ear requires operation in any case, and this operation can be combined with an exploration for the bony fistula and the recognition and treatment of the brain disease.

THE CHOICE BETWEEN THE ABDOMINAL AND VAGINAL INCISIONS IN THE OPERATIVE TREATMENT OF ACUTE PELVIC INFLAMMATIONS; WITH SOME REMARKS UPON THE TECHNIQUE OF THE VAGINAL OPERATION.

BY EDWARD REYNOLDS, M.D., BOSTON.

OUR modern conception of the clinical management of the several lesions which were formerly familiar to us under the collective title of pelvic abscesses is closely akin to the modern conception of the treatment of appendicitis. The question of whether or not to operate in a given case is decided upon substantially the same grounds, and the operative cases which especially concern us now may be divided in the same way: on the one hand, into the emergency operations to which we are forced during an attack by the serious condition of the patient and by our inability to check the disease by minor means; on the other, into operations done during the quiescence of the disease, or as we say in appendicitis, in the interval. With these latter cases the present paper has nothing whatever to do, and I hope that the discussion, like the

¹ Read before the Surgical Section of the Suffolk District Medical Society, March 17, 1897.

paper, will be restricted wholly to a consideration of the emergency cases operated upon during the attack.

One prominent difference is indeed to be found between the emergency operations of appendicitis and those which we are discussing here. In appendicitis the object of the operator is primarily the saving of the life of his patient by a safe evacuation of the pus; and, secondarily, the removal of the useless appendix in every case in which this is safely possible, in order to avert the danger of a recurrence. The primary object of the operations which we are discussing is exactly the same, that is, the safe evacuation of the pus; but the secondary object, the removal of the source of the disease, is modified by the fact that the organs which are in question here all fulfil important functions, and should therefore be saved whenever there is any reasonable chance of their return to health.

The situation of the pelvic organs of the female offer the operator upon these pelvic inflammations a choice between three distinct methods of attack: first, the total ablation of the genital organs of his patient by vaginal hysterectomy; second, the abdominal incision, evacuation of the pus, and if the patient's strength and the other conditions of the case permit, an inspection of the diseased organs and the removal of such portions of them as may be necessitated by their condition and permitted by the general condition of the patient; thirdly, a vaginal incision, the evacuation of the pus, in a few cases the removal of the diseased appendage through the incision, in a majority the chance of a cure by drainage of the diseased organ, and if this is not obtained, a radical operation at a subsequent time and by an abdominal incision. These three methods, and their relative advantages and indications, form the subject which I wish to discuss.

Vaginal hysterectomy can, in my opinion, be disposed of in a few words, if we remember the limitations of the question we are discussing; that is, that we are not opening up the question of the application of vaginal hysterectomy to tubes and uteri which have been destroyed by long-standing disease, but are considering simply its applicability to the acute inflammations when treated by operation during the attack. I think that no gynecologist of experience will disagree with me in saying that we have no method of external examination which, in the presence of acute inflammatory swelling, can definitely settle the question of whether or no a given set of appendages is beyond the possibility of a return to the normal; and it seems to me clear that without this certainty we cannot be justified in including among our methods an operation which begins by destroying the uterus without permitting the operator to investigate the condition of the appendages.

The choice between the abdominal and vaginal incisions for the purpose of evacuating the pus and, if it be possible and necessary, of removing the disease which is the source of the pus, is, then, the main subject of my paper.

The day has passed when any man may rationally declare himself an advocate of either method for all cases. In the last two years the vaginal operation has taken too firm a hold to permit of such a position. The choice between the two must be made partly by the pathological anatomy of the disease and partly by its topographical situation. The mass felt on bimanual examination may consist of effused lymph, pus, or other septic fluids; in the ovary as an ovarian abscess,

in a tube as a pyo-salpinx, in Douglas's fossa as an encysted peritonitis, or in the sub-peritoneal connective tissue of any portion of the pelvis as a true pelvic cellulitis, or, as I prefer to call it, phlegmon; and the first step in the decision is the establishment of an approximate diagnosis of the form of inflammation which is present.

In the furor over the importance of the tubes which followed the opening of the abdominal field for operative work, the very existence of pelvic cellulitis was denied by a majority of gynecologists; and the few who persisted throughout in their belief in its frequency now have the satisfaction of knowing that the denial of its existence by the mere abdominal surgeons was due to the fact that the existence of a pelvic cellulitis cannot readily be detected either by the eye or touch through the abdominal incision. It is undoubtedly seldom originated except as the result of a septic puerperium after abortion or labor; but there is strong reason to believe that a woman who has once been its victim may be liable to repeated attacks as the result of other causes, and that any one of these attacks may be of the severest grade; moreover, the work of the vaginal operators has demonstrated a degree of frequency of this affection which was not dreamed of by the warmest supporters of its existence ten years ago. Pelvic cellulitis, or, to use the better expression, pelvic phlegmon, can hardly be detected or treated through the abdominal incision, and it is here that we must draw the first line, that dependent upon pathology, between the abdominal and vaginal incisions. All cases of phlegmon must be attacked per vaginam.

The first step in the diagnosis is, then, the establishment or exclusion of the existence of a pelvic phlegmon. This will appear to the touch as a boggy mass behind the uterus, on one or both sides of the uterus, or, exceptionally, along the lateral wall of the pelvis. In either case, its outlines will be unlike those of any other mass in the pelvis, in that the thickening and boggy mass will be continued into the neighboring sub-peritoneal connective tissue; and if a careful search for such an extension is made under either, it will be rare that the existence of any considerable phlegmon can be overlooked. If a phlegmon is found, its presence may be considered an absolute indication for the vaginal incision; but in the other forms of pelvic inflammation the choice between the two operations is often a puzzling one.

The abdominal incision labors under the disadvantages, first, that clean peritoneum must ordinarily be crossed in the search for the pus, and that, however carefully we may wall off, this is necessarily a source of danger; secondly, that in these acute cases the element of shock is usually prominent during abdominal operations, and contributes in no small share to their mortality. Its sole advantage is that the radical excision of the disease is much more easy for the operator than by the vaginal operation. The vaginal incision labors under the disadvantage just mentioned of increased technical difficulty, but has the very great advantage that the septic fluids can be evacuated without any considerable risk of contaminating the general peritoneum, that it is attended by practically no shock, and that by it we can sometimes save organs which would have been sacrificed by the abdominal incision.

Our guide to the choice between these two methods must be found in the varying relations between two factors which must be weighed severally and con-

jointly in their relations to each individual case; that is, the general condition of the patient in its relation to shock, and the topographical situation or accessibility of the mass in its relation to the drainage or removal of the diseased organs.

Patients may be divided for our purposes, by general condition, into three classes: (a) those in an acutely dangerous condition, but in whom there are no symptoms of general peritonitis; (b) those in an acutely dangerous condition, but of whom it cannot be said with certainty that general peritonitis is not present; and (c) those who are seen at a time when they are still in good condition. In the first two classes the primary question of the removal of the dangerous condition by the evacuation of the pus is of paramount importance, while the prolongation of the operation necessary to a removal of the disease would be contraindicated in the operation by either incision; and since in these two classes the arrest of the sepsis is all that we can expect, the choice should be made by the existence or non-existence of the symptoms of general peritonitis.

(a) In the absence of such symptoms, there can to my mind be no doubt but that the absence of shock and the direct and dependent drainage of the vaginal incision render it by far the preferable operation, and I am confident that there are but few cases in which the mass is too inaccessible for the adoption of this method, so long as mere drainage of the abscess is all that is advocated.

(b) In the presence of the symptoms of general peritonitis, some surgeons would recommend euthanasia and a death-certificate. I believe, myself, that this policy is frequently more defensible on the ground of timidity and a regard for the surgeon's statistics than with regard to the patient's interests. In the first place, there are certainly some cases in which the symptoms are deceptive, that is, in which they precede the establishment of the actual peritonitis; and in the second place, we cannot now doubt that general peritonitis has occasionally been arrested by operation. I believe, then, that we ought not to allow such patients to die without operation, if it is acceded to after the fullest possible statement of its gravity; but I believe that in all such cases the incision should be made through the abdominal wall, that the condition of the general peritoneum may be known, and its cavity, if necessary, be washed or sponged out.

(c) In the third class, that in which the patient's condition is sufficiently good to permit of a radical operation should that be necessary, the choice between the methods is far less readily defined, and, indeed, seems to me one which must be determined upon principles which are not yet thoroughly established, but are still to a considerable extent *sub judice*. The grounds upon which the decision should be made and a provisional plan of action can, however, be stated.

It must be remembered that the vaginal operation stops short of the removal of the appendages in the great majority of cases, but that it differs from the antiquated procedure of tapping an encysted peritonitis in the fact that it not only opens and drains the encysted abscess in the freest possible manner, but also opens, washes and drains the suppurating tube or ovary which was the original cause of the encysted abscess; and that, moreover, the advocates of the vaginal method claim that patients are restored to complete health by this drainage of the diseased append-

age no less surely than by its removal. Thus Henrotin, in his latest utterance, states that he prefers to use the vaginal method even in cases of unruptured tubal or ovarian abscess, on the ground of saving ovaries and tubes which would have been removed by the abdominal operation, and supports his position by the recital of a case in which such an ovary was restored to complete health, and by an implied statement that he does not consider this result exceptional. That this opinion of Henrotin's is not wholly without foundation I can myself testify, for I have twice at least known the vaginal drainage of an undoubted pyo-salpinx to be followed by a restoration to complete health, as judged both by the symptomatology and by a bimanual examination. That in others of my cases a second and radical operation has been necessary may have been the result of an imperfect technique (for it must be remembered that the operation has only recently been well worked out); but I am inclined to believe that these happy results are exceptional, and to think, therefore, that when an excision of the disease can be safely accomplished it is far better for the ultimate interests of the patient. To me, therefore, as to all who hold this view, the only argument for the vaginal incision in patients whose condition would permit a radical abdominal operation is that its admittedly greater safety in dealing with virulent and accessible pus may in such cases warrant the acceptance of its lesser chances of a final cure.

For the present and provisionally, I am then inclined to believe that when the mass perceived by the fingers is high in the pelvis, the chance of its being an unruptured ovarian or tubal abscess which can be removed completely and without grave danger per abdomen, and the chances of its being an appendicitis, of its containing intestinal adhesions of a nature which should not be blindly dealt with, or of encysted collections of septic material which are so high as to be wholly out of reach of the fingers when inserted into Douglas's fossa through the vagina, are, when taken together, enough to make the vaginal incision as dangerous as the abdominal, even in acute and virulent cases. I should therefore say for the present that when the patient is in good condition and the mass is high in the pelvis, we should choose the abdominal incision.

When the mass is low in the pelvis, I believe that the arrest of the acute attack can, in the vast majority of all cases, be most satisfactorily and safely effected by the vaginal incision, but that what seems to me the greater probability of effecting a radical cure in the removal of the offending appendages by the abdominal method should lead us to prefer that incision when the condition of the patient permits and when the history of the case makes it probable that the fluids are not of a very virulent character, that is, in acute attacks which supervene upon long-standing pelvic diseases with but slight exciting causes. When, with a low situation of the mass, the history of the case renders it fair to assume that the contained fluids will be actively virulent, I believe that we should adopt a vaginal incision, and if the patient's condition permits, make every reasonable attempt to render the operation a radical one by at least securing thorough drainage of the affected organ. Finally, in this class of cases, in which the patient is in good condition, a combination of the two operations may be considered. Thus we may open a dependent collection of fluids per vaginam,

disinfect the cavity, and then after cleansing the hands and taking up a new set of instruments, open the abdomen, perform the radical excision, and drain through the vaginal wound; or, on the other hand, if when the abdomen is first opened, the adhesions prove to be so firm, the intestines so friable-looking, and the general look of the mass so uninviting that we feel discouraged from disturbing it, we may with propriety turn to the vagina, and open and drain from below, with the advantage of being able to watch from above, and thus the more readily avoid entering the general cavity; but this argument is to me theoretical, as I have not yet had personal occasion to use either of these combined methods, and am therefore unable to offer any practical opinion upon their value. The establishment of drainage through the vagina from above after opening the abscess by the abdominal incision is a somewhat similar, but a much more trifling procedure, with the results of which I have been well pleased.

TECHNIQUE.

The technique of the vaginal operation varies in accordance with its direction toward the cure of a phlegmon or of some other form of pelvic inflammation. As used for the treatment of phlegmon and for a few cases of unruptured pyo-salpinx it is throughout an extra-peritoneal operation; in all other cases it is intra-peritoneal from the beginning.

Phlegmon.—This question of whether the incision into a pelvic phlegmon shall or shall not be preceded by a curettage of the uterus is one which must be decided by the peculiarities of the individual case. As a general rule, when the septic endometritis which was probably the original source of the trouble is of long standing, it is best not to interfere with the endometrium, since the breaking down of nature's wall of protective lymph may well do more harm than can be accomplished by the removal of the detritus. In recent cases in which it is probable that absorption from the interior of the uterus is still actively going on, the main operation should be preceded by a thorough curettage. The canal of the cervix should then be temporarily occluded by a tight packing with sterile gauze and the vagina again thoroughly disinfected before the vaginal incision is made, thus guarding ourselves as far as possible against the dangers of sepsis, in case a mistake in technique or performance leads to an opening into the peritoneal cavity. This question settled, the posterior vaginal hysterectomy incision should be made with the knife, and carried through the submucous tissues and a little way up the posterior wall of the uterus, as close as possible to it, with the knife or scissors; but so soon as this has been done and the infiltrated subperitoneal tissues have been reached, the cervix should be firmly seized by a volsellum, which is used throughout the remainder of the operation to control the position of the uterus. The cutting instruments should be laid aside and the fingers should be pushed into every part of the infiltrated mass under the guidance of the sense of touch, great care being taken to make the dissection thorough and to reach and widely open every portion of the mass. Retractors may be used or not at the pleasure of the surgeon, but no other instruments are ordinarily employed during the latter part of the operation. The tearing should be kept as close as possible to the posterior wall of the uterus when in the median line and

as far forward as possible when towards the side of the pelvis, that is, when within the cavity of the broad ligament, the object of this precaution being, of course, to avoid opening the peritoneal cavity. In the presence of well-marked infiltration this danger is, however, avoided with somewhat surprising ease, and it is certainly surprising to see to what height in the pelvis we can safely penetrate by this method. Thus, I have successfully passed my fingers extra-peritoneally through a retro-uterine phlegmon until they were on a level with the fundus and began to turn forward over it, opening a number of disseminated foci of pus in the process, and a few minutes afterwards passing them out almost to the pelvic wall on each side through the cavities of the broad ligaments, in which I found several additional foci of pus. In this particular case, the most extensive that I have ever done by this method, the operation was followed by a chill and a rise of temperature to 104°, no doubt symptomatic of the opening of fresh tissues, but these symptoms subsided spontaneously within twelve hours, and the patient made a rapid recovery from what had been regarded, both by myself and by the gentleman who called me to the case, as a very critically dangerous condition. I feel confident that this patient would not have survived an abdominal operation.

May I quote one other unfortunate case in which a general surgeon of extended experience opened the abdomen for the relief of a pelvic mass which he felt, and which he rightly judged to be acutely septic; but on finding the abdominal cavity and all its contents in a normal condition, he closed it and put the patient to bed, in the belief that he had made a mistake in diagnosis. The patient's condition growing rapidly worse, he kindly asked me to see her a few days later. I found a pelvic phlegmon of about the size of an ounce bottle in the lower portion of the right broad ligament, which, at his request, I opened per vaginam, tearing up the tissues extensively and setting free numerous small collections of pus which contained a pure culture of streptococci. The patient improved considerably, but the operation had been delayed long enough to permit the establishment of a marked general sepsis, and she finally failed and died. Is not this case one in which the prevailing disbelief in the existence of pelvic phlegmon directly caused the death of the patient?

Even when pelvic phlegmon is absent, we may occasionally employ a similarly extra-peritoneal technique; that is, when the mass is not a phlegmon, is limited to one side of the pelvis, and comes well down into Douglas's fossa, it is always probable that we are dealing with an unruptured tubal or ovarian abscess in a low position, which we may be able to reach and drain extra-peritoneally. In such cases we should begin by an incision made at the side of the cervix along the base of the broad ligament, and if necessary, extended across the posterior surface of the cervix to the median line, in order to afford room. When this incision has been made and the cleavage plane of the subperitoneal connective tissues is reached, the finger can with care be carried up along one side of the cervix into the cavity of the broad ligament, without entering the peritoneum, and then made to tear its way upwards until it is certainly anterior to the abscess. If one finger of the other hand of the operator, or preferably the finger of an assistant, is then placed in the rectum, it is easy to satisfy one's

self, first, that the abscess rests between the two fingers, and, secondly, that it lies between the finger in the wound and the peritoneal cavity. A sharp-pointed pair of scissors may then be thrust into the sac and made by extending their blades to tear a wide opening. In some cases this can be done under the guidance of the eye by a careful and guarded use of retractors; in others it must be done by the sense of touch.

When the mass is not a phlegmon and is not so situated as to be clearly a tube and easily accessible from the front in the manner just described, an intra-peritoneal method must be adopted, and for this purpose Henrotin's incision is, I think, the best. After, of course, evertting out the uterus and stopping up the cervix, he makes the posterior incision for vaginal hysterectomy through the mucous membrane and sub-mucous connective tissues; then, from the middle of this incision, makes another cut running directly backwards along the median line to as near the position of the rectum as is deemed safe, and then carries the whole of this T-shaped incision directly through into Douglas's fossa. The wide space gained by this incision is then held open by drawing the cervix forward with a volsellum, while the rectum and posterior edge of the wound is held back into the hollow of the sacrum by the perineal retractor. The finger is then made to explore cautiously in all directions, under a combined use of the senses of sight and touch until the source of the trouble is found. If the case is one of encysted peritonitis, the finger should not only be passed through it in all directions until the operator is sure that every ramification of the abscess cavity has been thoroughly opened up, but should be especially directed towards finding the salpingitis which is the probable source of the trouble. If an enlarged tube or an ovarian abscess is found, this should be freed and drawn gently downward till it is in good view, and then opened, washed out, and drained with gauze; or if the conditions of the case permit, it may even be tied off and removed, though the opportunity to do this with safety must be extremely rare in acute cases.

GAUZE DRAINAGE.¹

BY FRANCIS B. HARRINGTON, M.D., BOSTON,
Festing Surgeon at the Massachusetts General Hospital.

THE effort to find a substitute for the sea sponge led to the very general use of cotton gauze. As a sponge it was packed into wounds to control hemorrhage and allowed to remain. It was soon found that it made an excellent drainage material in certain cases.

The modern use of gauze is one of the most important elements in the progress of abdominal surgery. By its aid a peritoneal area can be made an extra-peritoneal one in a few hours. Its presence sets up an adhesive peritonitis which will, if the gauze be properly used, divide the healthy from the diseased portions or make a safe channel from a diseased portion, like the stump of an appendix or an incised gall bladder, through healthy tissue to the surface.

Drainage may be either active or passive. Passive drainage is that form in which the material to be removed finds its way by gravitation to the outlet provided for it. Such drainage we have in the ordinary

tubular drainage material made of rubber, of glass, etc. These tubes are often indispensable, but they are passive agents. When they do not act by force of gravity they act merely by overflow or by *vis a tergo*. Active drainage we have when any kind of suction apparatus is used. These, however, are intermittent in their action or complicated and liable to injury.

The ideal drainage material is one which not only furnishes a channel for the removal of liquids but one which draws these liquids from all directions and which acts continuously. In the best cotton gauzes we have such a material. Gauze drainage acts not only by the force of gravitation but against this force. It will drain a dependent stump or a deep cavity in the abdomen. The value of gauze as a drainage material depends upon capillary action and siphonage. The absorptive action of gauze draws fluids into its meshes from every direction. Its capillary action carries these fluids over the edges of the wound, and then begins its action as a siphon. The longer the overhang of a gauze drain the greater will be its siphonage power. The amount of fluid which can be drained out of a cavity in a few hours is very great. In the abdomen gauze, if properly used, is of the greatest value. It is important, however, that the whole of an infected area should be filled with gauze. The wicks should extend to the farthest point of an abscess cavity or of an infected area. The gauze should be so placed that it separates healthy from unhealthy tissues. What then takes place? If the gauze be inserted dry every fibre of it at once begins to suck the fluids from the abdominal cavity. The movement of these fluids is towards the gauze mass and away from the healthy tissues. It is sometimes advisable to combine gauze drainage with tubular drainage. The value of gauze drainage in other parts of the body is often very great. Take, for example, a beginning palmar abscess. A patient, after intense pain and some swelling of the hand for a few hours, is operated upon, and the sheaths of the flexor tendons of palm are found distended with fluid. These sheaths are incised and the fluid evacuated. It is of the greatest importance to keep this wound freely opened and drained, and to drain especially the tendon sheaths. Any pressure from a drainage-tube is likely to cause sloughing of these delicate parts, which will result in a useless hand or fingers. It is here again that gauze drainage, in the form of wicks, can be used to the greatest advantage. It is not necessary that this gauze should be frequently changed. If a fine stream of sterilized water or a weak antiseptic solution be played upon the gauze once or twice a day it will clean it, and keep it in good drainage condition. The same treatment can be used in cleaning gauze in abdominal wounds after adhesions have formed.

Large free openings are the rule in operations in septic conditions. Gauze packing of these wounds not only acts to drain the wound but to prevent the rapid closing of incisions. Nature in her haste often closes wounds too rapidly unless prevented by packing.

What are the requisites of a gauze for drainage purposes?

It should be first of all clean and free from all fatty material. It should be soft. It should be free from ravellings and threads. It should be sterile.

The capillarity and the capacity for siphonage vary with different gauzes. Coarse gauze makes better sponges and a better drainage material than fine gauze. A gauze which has 26 threads in the warp and 22 in

¹ Read before the Surgical Section of the Suffolk District Medical Society, March 17, 1897.

the woof or filling to the square inch is none too coarse. These coarse gauzes are sometimes injured in the process of cleansing, so that the regularity of the fibres is destroyed. Such a gauze is inferior to one which has not lost its regularity. H. G. Hall, in a recent paper, has shown that the capillarity of gauzes varies greatly in different gauzes and even in the same roll of gauze. He also finds that the impregnation of gauze with various substances, as iodoform, carbolic acid, etc., decreases the capillarity. Morris, of New York, long since called attention to the inferiority of iodoform gauze for drainage material. Thayer, from his experiments, was led to believe the drainage value of iodoform gauze was so slightly less than that of plain gauze that it made little difference which was used. From my own experiments I should say that the drainage value of the best plain gauze is much greater than that of iodoform gauze.

In making drainage-wicks of large size which are to be used for large cavities, long strips of folded gauze should be used. These wicks should be so made that cut edges shall not leave bits of the material in the wound, for these ravellings may act like a silk ligature to keep up suppuration if they remain in the wound. For small wicks it is well to have a gauze tape. I have had such a tape made in various widths from one-third of an inch to three inches. This tape has a selvage on both edges. It cannot ravel. It is an excellent drainage material. It may be used in combination with large masses of drainage-gauze or with drainage-tubes. It is better to insert gauze drainage in straight lines rather than to fold it up in masses for two reasons: first, because it is more easily removed from a wound; and second, because it drains more quickly.

Drainage-tubes are essential in certain conditions; as, for example, the drainage of an empyema, the urinary bladder, the gall-bladder or the kidney; but usually a combination with gauze is very desirable. Gauze should not be so used that it causes a damming up of the secretions. It is unwise to pack with gauze a narrow sinus leading to a discharging cavity. It is an important question to decide how long you will allow gauze to remain in a wound. In this regard one should be governed by the patient's condition. Frequent changing of gauze is undesirable and unnecessary. In the abdominal cavity I allow gauze drainage to remain from three to four days. In aseptic wounds, where gauze has been placed solely to remove blood or serum it should be removed earlier, that is, in from twenty-four to forty-eight hours. The early removal of large masses of gauze is a painful operation, and should be done under primary anesthesia. At a late period when suppuration has begun it is much easier to remove. It is usually desirable in septic cases to replace the gauze removed by fresh pieces but in diminished quantities. If suppuration is very abundant, drainage-tubes can be combined with the gauze. The process now becomes one of cleaning up a sloughing cavity, and the presence of the gauze assists greatly in doing this.

HYPORHOPTRY AND VITATION OF THE HEART. —

In an account of an autopsy recently published in a daily paper it is stated that the medical examiner signed a certificate giving the cause of death as "congestion (passive) of the lungs and kidneys and hyporhoptry and vitation of the heart."

CONVERGENT STRABISMUS.¹

BY CHARLES H. WILLIAMS, M.D., BOSTON.

THE nerve centres which govern the accommodation and convergence of the eyes are closely related both in position and action; an increase of accommodation carries with it an increase of convergence, and *vice versa*; and a disturbance of this equilibrium is one of the principal causes of convergent strabismus.

In Donder's experiment a person with normal eyes looks steadily at a near object; a screen is then placed between this object and one eye, but no deviation takes place in the convergence of either; if, however, a concave glass is placed before the other eye an increased amount of accommodation will be needed in order to see the object clearly; the eye behind the screen will then be seen to turn more strongly inward in proportion to the increased effort of accommodation, while the eye with the glass remains fixed on the object. This condition is similar to that of young hypermetropes who are beginning at an early age to make use of their eyes for near vision. They require an amount of accommodation in excess of the convergence needed for seeing near objects, and if one of the eyes for any reason has less acuteness of vision or muscular power, as compared with the other, we often get a resulting strabismus; on the other hand, there are hypermetropes of all degrees in whom strabismus never develops, and many cases of deviation must be accounted for by amblyopia, by impaired muscular balance, or primary anomaly of binocular vision. Out of 612 cases of operation for convergent strabismus, reported by Dr. C. S. Bull,² 521 had simple hypermetropia and 58 hypermetropic astigmatism; my own experience does not give quite so large a proportion as this, but all observers agree that the percentage of hypermetropia in cases of convergent strabismus is very large. In the early stages of the trouble the deviation is often periodic or alternating, becoming in time more permanent, and it is during these early stages, while binocular vision can still be called into play, that we should endeavor to effect a cure; that is, get parallel visual axes, and, if possible, permanent binocular vision. If the treatment is delayed we may obtain a good position of the eyes by operation, but we very seldom get good vision in the squinting eye. Schweigger states that he has never seen any improvement in vision in a squinting eye after an operation, or even after separate exercising; and the reported gain is often due to the correction of errors of refraction rather than to the operation.

Convergent strabismus is usually developed in childhood, in some cases even before the second year, but in these very early cases, and in a few others, we often get a spontaneous cure; it is more common to have it first noticed in children of from two to five years of age, occurring when the child is tired or excited, or when the system is weakened by an attack of whooping-cough or other disease; and, if neglected, these attacks will often become more frequent and the convergence more permanent. Before deciding on our plan of treatment we should note the amount of deviation, its permanency, the effect of atropine on the convergence through its effect on the accommodation, and the refractive condition of the eyes as shown by retinoscopy or the upright image. If the patient is

¹ Read before the Massachusetts Medical Society, June 8, 1897, and recommended for publication by the Society.

² Transactions American Ophthalmological Society, 1895, p. 261.

old enough to give reliable answers, we should also ascertain the acuteness of vision of each eye and the relative power of the internal and external recti muscles. In general it may be said that it is not best to operate on children under six years of age, and not before the effect of atropine and glasses has been carefully tried; but the best results will often be obtained in children of from six to eight years of age, where the deviation has not yet become permanent, or binocular vision lost. If under atropine the eyes are found to be hypermetropic a nearly full correction with glasses should be given as soon as the child is able to wear them, even as young as four years of age, and the effect of the atropine should be gradually diminished while the glasses are worn. It has been found that about ten per cent. of the cases can be cured by optical means; but the success is closely related to the age of the patient and the care with which this treatment is carried out. The best measure of the strabismus is to get the angular deviation of the eye with a perimenter; but a rough estimate can be made by holding a millimetre rule at the margin of the lower lid of the squinting eye and noting the difference in the position of the centre of its pupil when the other eye fixes a distant object in front of the patient or is covered so that the squinting eye fixes it; one millimetre will correspond to about 5° of angular deviation. If after a thorough trial of the optical treatment no improvement results, it will be necessary to resort to operative measures, which is the final outcome of a majority of the cases, especially in adults. In most cases of periodic squint a simple tenotomy removes the trouble, especially if the deviation does not exceed 20° , and it is a common rule that one tenotomy will give about 15° of change in the deviation of the eyes. It is best to leave a *slight* convergence as the first result of the operation, for there is a tendency toward increased effect after a time, and a slight convergence will often pass into a practically parallel position. Noyes states that for a deviation of from 5° to 15° only one eye is to be operated on; from 15° to 30° , both will require it, but there should be at least a two weeks' interval before the second operation; for more than 30° both eyes may be done at the same sitting. In cases of permanent convergence the squinting eye, or in alternating cases the one which usually squints, should be first operated on. If there be marked deviation, especially with considerable amblyopia, and weakness of the external rectus of the squinting eye, it will often be best to make a tenotomy of the internal rectus and also an advancement of the tendon of the external rectus of the deviating eye, and if the result is not sufficient a tenotomy of the internal rectus of the opposite eye can be done at a later date.

During the last ten years a number of operators, especially Landolt and de Wecker, have recommended advancement instead of tenotomy in many of these cases. The advantages are that by advancement of the weaker externus when the internus has normal power, we add to the power of the externus and give it a better hold, without taking away from the power of the normal internus, and the eyeball is also left in a better position for rotation. The advancement operation is not so simple as the tenotomy and requires a longer after-treatment to get the tendon of the externus to take hold firmly in its new position. The conjunctiva is incised near the cornea vertically and dissected up from the externus muscle which is then grasped with

the forceps near its insertion and a small cut made at its lower border through which a blunt strabismus hook can be passed under the muscle. The muscle is then raised from the sclera and two sutures are passed through it and its surrounding tissues far enough from its border not to tear out easily. The tendinous attachment of the muscle to the sclera is then divided between the sutures and the eyeball, and while the eye is rotated by an assistant toward the cut muscle, the sutures are carried through the superficial layers of the sclera near the cornea to get a firm hold, and tied. The conjunctival incision is then brought together by fine stitches and a binocular bandage applied. The patient should remain in bed for five or six days, when the sutures can be removed, but the bandage should be continued for two days more to allow the healing to take place with as little disturbance from muscular contraction as possible. In advancement operations there is a tendency to get increased effect by the contraction of the cicatrix, and my brother wrote me last winter from Berlin that they were beginning to have there cases in which this contraction had produced so much deviation as to require another operation to remedy it. This, however, seems to be rather an excess of advancement in the earlier cases similar to that which occurred after the first tenotomies, producing an over-effect, and does not contraindicate the operation. The treatment of strabismus does not end with the operation; it is necessary to continue the careful correction of refractive errors with glasses, and often to supplement the glasses with orthoptic exercises which may train and strengthen the muscular action and help the maintenance of binocular vision.

Many cases of convergent strabismus are perplexing; it is often difficult to decide what operation will give the best results, or how much must be done to produce a given amount of alteration in the convergence as a final result, and we must not be disappointed if cases are found which need more than one operation, or in which we have to rely on our best judgment rather than on fixed rules.

Clinical Department.

REMARKS ON SECONDARY PUERPERAL HEMORRHAGE, WITH REPORT OF TWO CASES.¹

BY RAY W. GREENE, M.D.,

Visiting Physician to Worcester City Hospital, Gynecologist to Washburn Free Dispensary.

THIS puerperal hemorrhage is to be distinguished from the more familiar accident, post-partum hemorrhage. It is not of common occurrence, but is sometimes dangerous and even fatal. The literature of the subject is meagre.

The causes are twofold, constitutional and local. Under the first head we have

(1) Altered condition of the blood, as in purpura, septicemia and especially malaria.

(2) Psychic influences, for example, strong emotions, especially fear and grief.

Under the second general division we have

(1) The retention in the uterine cavity of some material (placental tissue, blood-clot or membrane)

¹ Read at the meeting of the Worcester District Medical Society, November 11, 1896.

which may prevent complete contraction, or set up congestion or favor sepsis.

(2) Accidental dislodgement of a thrombus from the placental site.

(3) Uterine inertia. This cause is classed by some authors under the first general division, namely, constitutional.

(4) Retro-displacements, producing congestion.

(5) Fibroids, especially when located in placental area.

(6) Malignant disease.

(7) Inversion of the uterus, a very rare secondary accident, unless associated with adherent placenta.

The disposition nature makes of any retained material is varied. In most cases, when the pieces are detached, uterine contractions force them out in a few hours. If small, gradual removal with the lochia accomplishes the same result.

Less often the retained portions, especially if adherent, become the starting-points for hyperplasia. "This hyperplasia is manifested as a greater or less thickening of the lining membrane or in the production of localized papillary, polypoid or fungus excrescences." This process is very frequently associated with some form of inflammation affecting the different normal tissues of the placental site, and in some cases the fibrinous element especially predominates.

Here we get the fibrous polypus and placental polypus. The fibrous polypus may originate with blood-clot, membrane or placental tissue. When the process is not complete enough to efface the placental character of its origin, the polypus is called placental. These growths are sometimes thrown off spontaneously without much hemorrhage. When hemorrhage does occur, it has been demonstrated that the amount does not depend on the size of the mass but on the degree of congestion or the accompanying inflammation set up by the irritation of a practically foreign body.

My two cases are similar and belong to the polypoid variety.

Mrs. C., in prime health, was delivered of her second child after a short normal labor. The child was born with a veil, so-called, but the membrane, though torn, was closely examined, so that none was left in the uterus. That the placenta itself was found intact, I am quite sure, since I remember examining it closely for the purpose of demonstration to a nurse who had never before been present at a confinement. Convalescence was normal. Patient was up and dressed after three weeks. About the thirty-first day a smart flowing began and increased. By the use of drugs and rest there was temporary relief. Thinking this flowing a possible catamenial period, aggravated by too active life about the house, I pursued conservative measures for five days, when the hemorrhage was followed by a watery, bad-smelling discharge, and the temperature registered 100° F.

On examination, I found protruding from the dilated cervix an irregular two-lobed mass, harder than normal placental tissue, and about the size of a hen's egg. There was not room to get my finger about the mass into the uterus. By a uterine sound I was neither able to get the depth of the uterus nor dislodge the offending mass. Owing to the alarmed condition of the patient and the tenderness of the abdomen, I was unable to feel the fundus. Under ether (the thirty-seventh day after the child was born)

the examination was comparatively simple and satisfactory. By bimanual examination, the fundus was found below the top of the symphysis, and the vaginal finger could easily enter the cervix beside the placental mass, and found it adherent to the uterine wall by a very tough fibrous pedicle about one-half inch in diameter.

This pedicle was broken off by the finger nail, and no attempt was made to curette off the rough stump of the pedicle, for the uterine wall was extremely soft, so that my finger, when attempting to sever the pedicle, slipped by it and penetrated the uterine wall to the peritoneal covering. This accident did not affect the convalescence, which was uneventful.

Within a few weeks of the case just mentioned, I confined Mrs. W., age thirty-six, of very nervous temperament, who had during this third pregnancy been much run down physically. Since the first pregnancy there had been extensive varicose veins of the legs and thighs, and during this pregnancy much pain and inconvenience were caused by this condition, worse than ever before. The labor was normal, with rapid second stage. The placenta and membranes came away intact, according to the notes taken at time of labor. Then followed a smart hemorrhage, which was quickly controlled by hot injections and friction over the fundus. The lochia was natural in quality and amount. The convalescence progressed normally, but slowly, owing to general debility, till the eighteenth day, when profuse flowing started up without any special exertion. On my arrival, two hours later, I found the patient in bed (which had been raised at the foot). The bedding under the exhausted patient was literally soaked in blood. It would be impossible to estimate the amount of blood lost. There was abundant evidence of a serious hemorrhage from the uterus. The nurse and neighbor present were alarmed, and the patient was blanched and unable to speak above a whisper. The pulse was thready at 120 beats per minute. On examination, I found but little flowing from the vagina, which was filled with large clots. In the softened and dilated os I felt a mass about one inch in diameter and two and one-half inches long, held fast to the wall of the uterus by a fibrous pedicle one-half inch in diameter. I dislodged the mass with a dull curette, washed out the uterus with hot antiseptic solution, gave ergotine under the skin and made the patient comfortable in a dry bed. As this affair happened after dark, I was handicapped with poor light and by lack of intelligent assistance. In my haste to get the patient comfortable I had mistaken a blood-clot in the washings for the polypoid mass. For, much to my chagrin, I did not find the mass sought till two days later, when it was expelled from the uterus, giving much pain to the patient. Fortunately there was no return of the hemorrhage. The convalescence was slow, owing to the general debility and great loss of blood.

Two questions have been asked me in regard to these cases:

(1) May not these polypoid growths be independent of the puerperal state?

I am confident that the mass in the first case contained placental tissue, and, I think, originated from a portion of adherent placenta, probably succenturiata, since a close examination of the uterine side of the placenta, at least, showed it to be intact.

Of the second case I am not so certain. It is more

likely, however, that the polypoid mass originated with some shred of membrane or clot of blood, rather than an ordinary fibrous growth independent of the puerperal state.

The second question relates to treatment. Is it advisable to explore the cavity of the uterus in every case when we know that *small* fragments of the placenta or membrane are left behind?

Usually I would follow the conservative plan of trusting nature to expel them; but, on the slightest provocation, either by reason of hemorrhage or suspicion of sepsis, the uterine cavity should be explored and made clean as possible, in accordance with modern antiseptic methods.

Medical Progress.

RECENT PROGRESS IN SURGERY.

BY H. L. BURRELL, M.D., AND H. W. CUSHING, M.D.

EXPERIMENTAL RESULTS WITH ANTISTREPTOCOCCIC SERUM.

Petruschky¹ reports that his experiments with cultures of streptococci and an antistreptococcic serum sent to him by Marmorek have not obtained the same promising results which that investigator reported. In the first place, he found that a dose stated by Marmorek to be absolutely fatal killed his rabbits only exceptionally. In fact, two of his own cultures of streptococci, which he had grown for two years, proved to be more virulent, so that their actions were not checked by antistreptococcic serum, although the latter was injected within twenty-four hours of the time of infection. The author, under the circumstances, thinks he is justified in his conclusions (1) that the therapeutic action of the serum is not yet to be recommended in man; and (2) that up to the present time there is no certain proof of the possibility of serum-therapy in streptococcic infection.

EFFECTS OF ETHER ON THE BLOOD.

The author of this paper, Von Lerber,² bases his conclusions on examinations of the blood of 101 patients. One or two examinations were made before etherization, and from two to four examinations afterward.

The quantity of hemoglobin was compared in 98 cases. In 65 cases it was the same after operation as before; 19 times there was an increase, 14 times a diminution, but in only two instances did this amount to 10 per cent., and in these there was great loss of blood at the operation. Ether, therefore, does not affect the quantity of hemoglobin.

The red blood-cells were counted in 101 cases. In 55 cases they were increased, in 42 diminished, and in four there was no change. The gain and loss were in most cases only temporary. So that it may safely be said that ether has no deleterious influence on the red blood corpuscles. A spectroscopic examination of the urine in 83 cases failed to show any increase in urobilin. This is further evidence that the red blood-corpuscles were not destroyed.

In 96 cases the white blood-corpuscles were increased; in five they were diminished. In three of these latter the opening of abscesses (which had caused pathological leucocytosis before the operation) sufficiently explained the decrease in white corpuscles. In one case the decrease seemed due to rapidly approaching death, and in the other case the decrease was insignificant. The author concludes that etherization often occasions a marked leucocytosis.

THE APPLICATION OF SCHLEICH'S METHOD OF COCAINIZATION.

Gottstein³ published results of cocaineization by the method of infiltration in 118 operations. Nearly one-half of these were for the extirpation of tumors. There were eight cases of resection of the vas deferens, two cases of strangulated hernia, ten gastrotomies, and several exploratory laparotomies. One advantage of this method is that the patient can usually get down from the table immediately after the operation, so that hypostatic pneumonia, which so often follows other operations in feeble patients, is avoided. It was a great pleasure to observe how slight a reaction followed these "major" operations. As far as possible an Esmarch bandage was used after the injections were made. The anesthesia usually lasted thirty minutes, sometimes still longer. In only two cases was there any evidence of cocaine intoxication.

THE SURGICAL TREATMENT OF FOCAL EPILEPSY.

Sachs and Gerster⁴ contribute a paper which presents a critical analysis of 19 cases operated upon by the authors. Of these, three are reported as cured, five as improved and eleven as unimproved. Of this last group three died as the result of the operation. The authors concede that surgical procedures will avail but little in the majority of cases. In all of the cases in which no improvement resulted, the operation was not undertaken until many years had passed after the initial trauma, and after the beginning of the epilepsy. They conclude that if a long period of time has elapsed, all operative procedures will prove equally unavailing. As a result of their study of these cases, the paper closes with the following conclusions:

(1) Surgical interference is advisable in those cases of partial epilepsy in which not more than one or, at the utmost, two years have elapsed since the traumatic injury or the beginning of the disease which has given rise to the convulsive seizures.

(2) In cases of depression or other injuries of the skull surgical interference is warranted, even though a number of years has elapsed; but the prospect of recovery is brighter the shorter the period of time since the injury.

(3) Simple trephining may prove sufficient in a number of cases, and particularly in those in which there is an injury to the skull or in which a cystic condition is the main cause of the epilepsy.

(4) Excision of cortical tissue is advisable if the epilepsy has lasted but a short time, and if the symptoms point to a strictly circumscribed focus of disease.

(5) Since such cortical lesions are often of a microscopical character, excision should be practised even if the tissue appears to be perfectly normal at the time of operation; but the greatest caution should be exer-

cised in order to make sure that the proper area is removed.

(6) Surgical interference for the cure of epilepsy associated with infantile cerebral palsies may be attempted, particularly if too long an interval has not elapsed since the beginning of the palsy.

(7) In cases of epilepsy of long standing, in which there is in all probability a wide-spread degeneration of the association-fibres, every surgical procedure is useless.

A METHOD OF DEFINING THE FISSURE OF ROLANDO.

Morison describes the following method for locating the fissure of Rolando:⁵

"The measurements may be made with a piece of sterilized silk marked off by knots to form the triangle, or by defining the sides of the triangle by means of the surgeon's finger, whose length is already known. A point is taken half-way between the glabella and the external occipital protuberance, and the breadth of the little finger behind it (about half an inch) indicates the apex of the triangle. An isosceles triangle is then mapped out on the scalp; its sides are three and three-quarters inches long. One lies in the middle line forward from the point mentioned above. The base measures four and one-eighth inches, and is anterior. The posterior side of the triangle is over the fissure of Rolando. Trigonometrically the apical angle of this triangle is $67^{\circ} 27' 52''$, and this is practically identical with the angle formed by the fissure and the middle line of the skull worked out by other methods, and, from an examination of a large number of skulls of various sizes, is constant and correct."

THE MORTALITY OF HARELIP, WITH AND WITHOUT OPERATION.

Fahrenbach⁶ writes of 210 cases of harelip, which were operated upon in Gottingen from 1885-95. Rejecting the too minute classifications of cases which some authors have made (Stohwasser enumerates thirteen different types), he has arranged his material in four groups, according as the cleft in the lip was single or double, and with or without complications in gums or elsewhere. The different operations performed are accurately described and illustrated, but an especial interest attaches to the mortality. The immediate results were satisfactory. In 166 cases the operation was entirely successful, and of the 210 cases only nine died—about four per cent.; but when the cases were followed for a considerable time the author found the mortality to be discouraging. This is especially true of the cases with complications. Thus, the cases of single harelip with complications showed a mortality in two weeks of 5.7 per cent., which in three months was doubled, and at the end of one year had risen to 30 per cent. of all the cases of this class. The death-rate for bilateral cases with complications was 17 per cent. for two weeks, and the same for three months, but was over 50 per cent. at the end of the year. Including all the cases operated upon, the mortality at the end of two weeks was 7.5 per cent., at the end of three months 10.7 per cent., and 32.3 per cent. at the end of a year; and by deaths after one year these figures were raised to 41.8 per cent.

According to these figures one-third of all children

operated upon for harelip fail to live a year, and probably not one-half of them live to grow up. But these figures are to be compared not with those of healthy children, but with those of cases of harelip without operation. Just what the mortality among such deformed children is, is not known, but it must be high. For example, in one hospital 14 per cent. of the patients with harelip died before they could be operated upon. Generally speaking, the earlier the patients are operated upon the more of them succumb in the succeeding months; but this the author considers due to the fact that many of the children would not in any case be able to live. He is an advocate of an early operation (sixth to eighth week) for the lip, leaving until later the treatment of any deeper deformity which may be present.

SURGICAL TREATMENT OF BASEDOW'S DISEASE.

Professor Mikulicz, of Krakau, is favorably impressed by the operative treatment of this affection. His conclusions are based on the analysis of 11 cases. Nine had exophthalmos; all tachycardia, with pronounced nervous and mental symptoms. Most of the patients also showed typical trophic disturbances. There were seven cases of diffuse hyperplasia, three with circumscribed nodules; and in one case (a cyst with five) the trachea was compressed, causing dyspnea. Two were treated by ligature of the thyroid arteries, three by enucleation, five by resection (three bilateral, two unilateral). There were no deaths. Six were cured (after one to nine and one-half years). Four were much improved, one slightly improved (by ligation, unilateral). Improvement of symptoms continued for a long time after operation. For diffuse goitre ligation of the four thyroid arteries is recommended; for circumscribed nodules and cysts, "Socin's" enucleation; and resection for those cases not benefited by ligation (it is much more difficult and dangerous than in simple goitre).

The rate of improvement after operation is varied—the symptoms in some cases having ceased entirely in a few weeks, in others months and even years are required. The psychical and nervous symptoms usually disappear first; for example, restlessness, insomnia, vertigo, cardiac palpitation, etc. The disturbances of circulation cease next; the exophthalmos and trophic derangement last. Mikulicz thinks that the most of the symptoms are due to auto-intoxication by thyroid products, and that the first effect of the operation is to reduce the supply of toxic substances. He considers operative treatment indicated where medicinal treatment has failed and where dyspnea is present.

PRELIMINARY RESECTION OF THE FIFTH COSTAL CARTILAGE IN ORDER TO APPROACH THE PERICARDIUM.

Durand⁸ recommends this method of reaching the pericardium in operations on this structure. This operation was first suggested by Ollier. Some writers advise the resection of the sixth cartilage also, but Durand has found the space afforded by removal of the fifth entirely sufficient.

The author recommends the resection of the fifth cartilage preliminary to simple aspiration. He lays stress on the chance of serious injury from a puncture, even with a small needle, through an intercostal space,

⁵ British Medical Journal, 1896, No. 1868; American Journal of Medical Sciences, January, 1897, p. 116.

⁸ Revue de Chirurgie, 1896, No. 6; American Journal of Medical Sciences, December, 1896, p. 718.

as the operator does not know where his needle is going. The operation has its chief indication, however, in performing pericardotomy for purulent pericarditis.

The chief difficulty in the operation is the costo-mediastinal cul-de-sac in separating the sternal end of the cartilage. In the tuberculous the cartilage may be very adherent. In those who have had no inflammatory infection of the lungs the procedure is simple. In some cases the recognition of the pericardium will be difficult. The perichondrium is to be removed with the cartilage.

Technique.—(1) The incision is made on the fifth costal cartilage, parallel to it, and from six to eight centimetres long. It should commence in the median line. (2) Rapid denudation of the cartilage by a bistoury. (3) Resection of the cartilage by separating the sternal attachment and lifting from behind forward. Durand adds ligature of the mammary vessels. Secondary ulceration or accidental perforation are thus provided against. The fingers then loosen the triangularis sterni. The border of the sternum may be removed by the gouge if more space is required.

OPERATIVE TREATMENT OF PHLEGMONS OF THE POSTERIOR MEDIASTINUM.

Obalinski⁹ after reviewing the history of these operations, reports five cases of his own, making in all a total of 13 cases which had the similarity that in all a resection of the ribs was made near their spinal articulation, and the costal pleura dissected up from the heads of the ribs and the thoracic vertebrae, thus permitting an access to the vertebrae themselves or to the posterior mediastinal space. The shape of the incision the author does not believe is essential. The dissection of the costal pleura from the bone was successfully performed, with the exception of two instances in the living patient, in which the author tore the costal pleura and produced a traumatic pneumothorax; the wound, was, however, closed with sterile gauze; during the remainder of the operation no infection ensued, and the only result was a pneumothorax, which was not purulent, and passed off in one or two days after the operation.

As special indications for this operation the author gives these: (1) a cervical abscess which leads down into the posterior mediastinum or is the outgrowth of a mediastinal abscess; (2) an abscess originating near the spine; (3) a fistula in the lumbar or thoracic region; (4) a foreign body in the esophagus whose exact location we know, that is, into which wall it has penetrated.

TREATMENT OF CICATRICAL STRICTURE OF THE ESOPHAGUS.

F. Peterson¹⁰ reports the successful treatment of a badly constricted esophagus by the combined method of gastrostomy and gradual dilatation from below. The strictures were caused by caustic potash. One was at the level of the bifurcation of the trachea, and one near the cardiac orifice of the stomach. A gastrostomy was done two months after the accident with some relief. Four years later the Kraske dilatation was done. The upper stricture was then permeable

to a No. 28 sound. The patient was told to swallow a silk thread knotted at its ends. After this reached the stomach, which occurred in about five minutes, it was brought out through the gastric opening by flushing the stomach with water. As the water flowed from the stomach the end of the thread was washed out with it. To this end an ivory olive was attached, and to this another thread 50 centimetres long. To this latter thread a still larger olive was fastened. These were then drawn upward through the esophagus by pulling on the oral end of the thread. In this way the strictures were gradually dilated from below, beginning with No. 13 and using successively 15, 18, 20, 23, 25 and 28. When the dilatation reached 28, the passage of sounds from above was resumed, which were gradually increased in size to No. 54. The patient continues to pass No. 48 himself every three weeks, which is easily accomplished.

PATHOLOGY AND TREATMENT OF GUN-SHOT WOUNDS OF THE ABDOMEN.

Klemm¹¹ (Riga) has written an interesting monograph on this subject. He reviews the literature of the subject, the results of his own experiments on dogs, and presents his conclusions from both. They correspond to all general opinions held at present by American and German Surgeons. He does not believe in the expectant method of treatment advocated by the French, especially Reclus, who claims that this shows a lower mortality; that the prolapse of the mucous membrane through perforations in the hollow viscera plugs the wound till plastic exudation seals it. Klemm found that the plug so described occurred, but that it did not prevent leakage of intestinal contents when the slightest pressure was made. This was also the clinical experience of Sonnenberg and Von Bergmann. Klemm also found that the abdominal viscera were perforated in a majority of cases. In 152 clinical observations of Lück only three escaped without injury of viscera. Local symptoms of injury were noted only eight times. The general symptoms of shock or beginning peritonitis were far more frequent.

The size of the wound was determined by the angle of the direction of the striking bullet with the surface struck and by the diameter of the intestine at the point struck. When death is not immediate from hemorrhage or shock, it is caused by septic intoxication from the toxins formed by the germs in the blood-clot which is always present. Adhesions may occur, abscesses from which sooner or later rupture and cause death. Klemm condemns Senn's gas test, which he claims increases the danger of fecal extravasation. He advocates immediate operation in all cases in which the patient's condition permits it. His plan of operation corresponds with that commonly followed by American surgeons, namely, to explore the wound of entrance, and if it is found to have penetrated the abdominal cavity to open it at once. He considers the presence of peritonitis or weakness due to septic intoxication as contraindications.

(To be continued.)

MR. HEATH TO LECTURE IN SAN FRANCISCO.—Mr. Christopher Heath, late President of the Royal College of Surgeons, England, has accepted the invitation to deliver the second course of Laue Medical Lectures at Cooper Medical College, San Francisco.

Reports of Societies.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

PAUL THORNDIKE, M.D., SECRETARY.

REGULAR Meeting, March 17, 1897, the President, DR. H. L. BURRELL, in the chair.

DR. F. B. HARRINGTON read a paper on

GAUZE DRAINAGE.¹

DR. HERBERT J. HALL, of Marblehead: I would like to add, in favor of Dr. Harrington's tape, some points which have come up in the course of my experiments, and I think they will be shown very clearly in the drawing. In the ordinary loose-meshed gauze we have as many threads running transversely as longitudinally. Now if a gauze sponge is tucked into an appendix abscess, and capillarity begins, we have acting, not only the longitudinal fibres out of the wound, but the transverse fibres all about the wound, and each of these transverse fibres carries in the wrong direction, not up and down as we wish. That is the disadvantage, as far as I have been able to make out, of ordinary open gauze in the drainage of cavities. In Dr. Harrington's tape the lateral distribution of the fluid is very slight, cannot go beyond his selvages, which are close together, so that capillarity when it occurs is in one direction—up and out of the wound, whereas that certainly (theoretically, at least) is a disadvantage of the ordinary open gauze in drainage.

In my experiments I have found, as Dr. Harrington has said, that iodoform gauze is not as good a drainer as the ordinary plain gauzes. We are very apt to err in making these experiments, and the only way I could prove that iodoform gauze was a poor drainer was to take a strip of plain gauze and weigh it, then subject it to capillarity by immersing one end under given conditions for a given time in water and then weigh it again. The difference in weight showed in a fair way the capillarity of that strip of gauze. If I took that same strip after drying it and impregnated it with iodoform, I found that its capillarity was decreased about one-third. That is a pretty conclusive experiment, and repeated in enough cases showed that iodoform decreases the capillarity of any gauze.

Dr. Harrington spoke about the difference between moist gauze and dry gauze in the drainage of cavities. It is a matter of common observation that if a perfectly dry sponge, one that has been baked and is brown, is thrown upon water in a basin, it will float. That we see frequently enough; and that a moist sponge, if thrown upon water will sink at once. This led Gerster, in his "Antiseptic and Aseptic Surgery," to state that moist gauze is a better absorber than dry gauze. That is a mistake very easy to fall into. I started out to prove that to be the case, but was obliged to arrive at another conclusion. If you take a strip of plain non-sterilized gauze and get its capillarity, that is, make note of the amount of water it will absorb, and take that same strip and sterilize it by steam in the ordinary Arnold sterilizer, and give it the same test, you will find its capillarity has not been changed, that it will absorb precisely as much water as before. If you now take the same strip of gauze and bake

it brown and subject it to the test under the same conditions you will find it will absorb the same amount of water. Also if you will weigh a strip of ordinary unsterilized gauze dry, and then get its capillarity dry, then moisten it, weigh it again and subject it while moist to the same conditions, you will find that the moist gauze absorbs not more and not less than the dry gauze; that is, the moisture in the gauze does not affect its capillarity; it will absorb just as much water whether moist or dry.

DR. A. T. CABOT said that he thought that the consistency of the fluid was an important element in the selection of the kind of drainage. A gelatinous fluid like thick pus or like blood was much more difficult to remove by the capillary action of gauze than the thinner serous fluids thrown out immediately after an operation. When an abscess is opened and the cavity is thoroughly packed with gauze, there is often afterwards very little pus excreted. The irritation and pressure of the packing sets up a healthier action, and the fluid thrown out is usually serous and readily carried away by the gauze. If, however, you have an abscess or effusion of blood deep in the pelvic cavity, you have a condition in which aspiration by gauze is less reliable, as the gauze gets quickly clogged with pus or blood, the gelatinous character of the fluid ruining the capillary action. It is also to be remembered that in the abdominal cavity drainage can almost never be said to be passive, in that this cavity is surrounded by muscles constantly in contraction, and is filled with intestines which are in motion or undergoing changes in volume, so that there is constant intra-abdominal pressure forcing out fluids even when the drainage-tube is not in a dependent position. If, for instance, after laparotomy you put a glass drainage-tube to the bottom of the pelvis, on sucking the tube out next morning you rarely find more fluid than the drainage-tube itself will hold, the rest having been forced out and then overflowed on the dressing.

He thoroughly agreed with Dr. Harrington in regard to the value of gauze drainage when used immediately after operation, and said that he regarded Dr. Harrington's experiments upon the action of different kinds of gauze as very valuable and interesting, in showing that iodoform gauze has a degree of usefulness in walling off and protecting uninfected parts from contact with septic fluids, even greater than he had before supposed.

DR. E. W. CUSHING: I think these tapes will fill a long-felt want. I do not quite agree with the opinion that gauze drainage will always drain the abdominal cavity satisfactorily; and yet it is also true, as Dr. Harrington has said, that in many cases it is extremely desirable to pack a cavity. The use of the Mikulicz drain, where there is a sac of gauze outside the gauze strips, allows us to have the advantages both of packing to check oozing and hemorrhage and of drainage. When the Mikulicz drain is used, it is not easy to get the sac out before several days; and when it is taken out, it is a matter of observation that there is apt to be a considerable collection of thick fluid below which has not drained away. I have often found it convenient to combine the two systems and put a tube just behind or in the middle of the Mikulicz sac. I think that is a great advantage, because you are able to have the fluid sucked out and avoid most of the soiling of the dressings; and when it is desirable to remove the tube and the packing, they may be removed

¹ See page 150 of the Journal.

and still the sac of the Mikulicz drain is left in. You can be sure you are draining the cavity. The glass tube or rubber tube may be used. I think that combination of the Mikulicz sac with the tube in the middle of it is the most satisfactory for draining the abdominal cavity, in cases in which anything more than a simple glass tube is required.

DR. HARRINGTON: I did not wish to be understood as saying that I should never use tubular drainage. I do use it in a certain number of cases, but I must admit that the number is not large.

TUBERCULAR KNEE-JOINTS.

DR. NICHOLS: I have to present two specimens, with drawings of tubercular knee joints, that illustrate the origin and extension of the process. Virchow has stated that in all tubercular joints the process arises in the bones. All of the surgical and orthopedic textbooks at present state that a very large proportion of the tubercular lesions of the joints begin in the synovial membrane. In examining nearly a hundred tubercular joints during the last two and a half years, and having this point constantly in mind, I have seen only two joints that even simulated a primary synovitis. These two cases I have to exhibit. In the other cases there was no question but what the process began in the bone and then extended to the synovia.

One of these cases is a tubercular knee from a woman of sixty. The symptoms lasted for a year, and the knee was finally amputated. The entire joint was received, including the tibia, fibula, femur and patella. The synovia was thickened and studded with miliary tubercles, but, with very careful examination, it was impossible to discover any connection with a bone focus. Sawing open the femur, a caseous focus was found in the end of that bone, about an inch in diameter; and this focus was obviously older than the process in the synovia, and opened into the joint at the insertion of the crucial ligaments.

The second case was received less than a month afterwards. It is a knee-joint from a man about twenty years old, which was excised. The specimen included all the bones of the joint except the tibia. The synovia was thickened and everywhere studded with miliary tubercles, but no connection with any bone focus could be made out. Sawing open the tibia and femur, no bone focus was found; but on opening the patella there appeared a small caseous focus, just at the insertion of the quadriceps, nearer the superficial than the joint surface, and older than the process in the synovia. This focus connected with the joint at the top of the patella. No other case examined, out of nearly a hundred in all, failed to show a primary bone focus.

It is, of course, impossible to say that primary tuberculous of the synovia does not occur, but it is fair to say that it occurs much less frequently than the textbooks represent. It is also certain that it is impossible at an operation to determine whether the process began in the bone or in the synovia unless every single bone involved in the articulation is carefully examined to a very considerable depth.

The tubercular process in the knee-joint appears to begin almost always in the epiphysis, near the epiphyseal line, with the formation of single tubercles which afterwards fuse; the trabeculae are dissolved and a "tubercular abscess" is formed, which extends peripherally, usually toward the joint. The cartilage is

eroded at some point, oftentimes at the insertion of the crucial ligaments, and the tubercle bacillus enters the joint, although it may be impossible to determine the point of entrance without opening the bones. The bacillus is diffused over the joint in the synovial fluid and miliary tuberculosis of the synovia is produced. Then the synovia may thicken into a dense tubercular granulation tissue, or may project into the joint as thick folds, the "villous" joint. The thickened synovia may extend over the surface of the cartilage as a dense membrane, thickest at the advancing edge. Wherever the membrane extends the cartilage beneath is destroyed and the ends of the bones are eroded. Ultimately only small islands of cartilage are left, the articular ends of the bones are destroyed, and subluxations occur.

DR. E. REYNOLDS read a paper on

THE CHOICE BETWEEN THE ABDOMINAL AND VAGINAL INCISIONS IN THE OPERATIVE TREATMENT OF ACUTE PELVIC INFLAMMATIONS, WITH SOME REMARKS UPON THE TECHNIQUE OF THE VAGINAL OPERATION.²

DR. BURRAGE: I am glad to have heard Dr. Reynolds's paper, as it is on a subject that has interested me a great deal for the past two years. Now that the vaginal route of operating has been so much exploited, it behooves us to lay down lines of procedure to be followed in any given case of peltic disease; and especially is this true in acute pelvic inflammation.

The discussion is limited, I understand, to emergency operations in severe cases of acute pelvic inflammation. Dr. Reynolds has spoken of the routes of septic invasion in the pelvis, that is, by direct transmission of the poison through the tubes, through the lymphatics into the broad ligaments and pelvic lymph glands and through the veins. We must remember that it is possible to have an inflammation of the pelvic cellular tissue, a phlegmon, without involvement of the tubes to any appreciable extent, an important point to be kept in mind in contrasting a conservative with a radical operation. I think we ought to consider the relative virulence of the different forms of acute pelvic inflammation according to their origin; that is, that the septic inflammations with the recently pregnant uterus are the most serious form, that those from operations on or injuries of the non-pregnant uterus are less serious, and those dependent on gonorrhea the least serious. Acute exacerbations of chronic inflammations are, as a rule, less virulent than those arising from fresh infection, but may, however, progress to a fatal termination.

I assume that Dr. Reynolds refers in his paper to some such case as this in speaking of operation in the attack:

A woman acutely sick with a temperature of 102° to 104°, pulse of 120, and rapid respiration. A mass in the pelvis of indefinite outline and dimensions, and, because of the great tenderness of the parts and rigidity of the abdominal walls, difficult to diagnose exactly. We rule out appendicitis, should the signs of this affection be negative, by falling back on the symptoms. The attack of acute pelvic inflammation is apt to be less explosive and less severe locally and generally than the attack of appendicitis. Then there is usually a history of previous uterine symptoms in one case

² See page 146 of the Journal.

and of intestinal disturbance in the other. The proper operative procedure in such a case is, in my estimation, to curette the uterus, open the cul-de-sac and drain both the uterus and the cul-de-sac with gauze. I should reserve the abdominal operation for masses high up in the pelvis and inaccessible from the vagina, and for undoubted cases of general peritonitis.

As has been said, it is not necessary to remove a diseased tube to effect a cure. That may be effected later at the time of election. What is needed is drainage. No one would choose an acute inflammatory attack as a suitable time for a radical operation in any other domain of uterine surgery. Why should the uterus be removed for an acute peri-uterine inflammation? It has been urged that by removing the uterus the drainage is better, and troublesome hemorrhage can be more easily controlled. To my mind removing the uterus adds to the shock, besides sacrificing an important organ that may be restored to usefulness. There is every reason to believe, as the reader has stated, that early drainage will permit later of a restoration to health of a diseased uterus and tubes.

Contrasting the vaginal with the abdominal operation, it is my opinion that with the former the patient experiences less shock; there is less disturbance of the intestines; only a corner of the peritoneal cavity being opened, the least amount of peritoneum is affected. In many cases the peritoneal cavity is not opened. Even where the intestines are exposed the pus is in many instances sterile, and there is no infection. The drainage is down hill, and is nearer to the source of sepsis than in the abdominal operation. Greater familiarity with operating in this field will make the vaginal operation easier of performance. Abdominal section in puerperal sepsis is a very fatal procedure. If any other measure will give better results it ought to be tried.

As to technique, I do not operate just as Dr. Reynolds does. I make the incision in the vagina with scissors, first catching up a fold of the vagina with two tenacula and cutting between them. The vaginal wound is then enlarged laterally by cuts with the scissors, and the operation proceeded with by dissecting into the mass of exudate by means of the finger and the closed scissors. Operating by the vagina has taught me something as to the treatment of pelvic abscesses, that is, that it is safer to open abscesses in the way just described than to puncture from the vagina with aspirating needle or trocar. I am totally opposed to puncture of pelvic exudates with needle or trocar for diagnostic or other purposes, as being dangerous. There is little chance of wounding the ureters or rectum if one operates as I have said, keeping in the median line and close to the uterus. The opening should be large enough to afford free drainage. Should there be hemorrhage, the intestines may be walled off with a plug of gauze, the patient placed in the Trendelenburg posture, and by the aid of a long spatula to raise the anterior vaginal wall and uterus, the interior of the pelvis inspected and the bleeding-point seized with forceps.

It seems to me to be safer to curette the uterus in every case before making the vaginal incision, even if a previous curetting has been done by another medical attendant.

DR. ENGELMANN: I have been much interested in the calm and judicious presentation of the subject by Dr. Reynolds, and thoroughly endorse all he has said in favor of vaginal interference; but he has hardly said

enough: Operation by this route, be it by incision and drainage or by partial or total removal of diseased tissues, is indicated more often than abdominal section, and is more generally applicable in acute pelvic inflammation.

In emergency cases we have no choice; the patient is then debilitated, with high temperature and feeble pulse, not likely to survive a laparotomy, whilst vaginal incision gives relief and may cure. A comparison of methods would be superfluous, if limited to these extreme conditions; but this Dr. Reynolds has not wished to do. As I understand him, he has confined himself to acute pelvic inflammations in which the knife is positively indicated; and in these cases it is unjust to entirely exclude hysterectomy, as he would have us do, if we are fairly to present the advantages of vaginal methods, since it may be forced upon us in the course of the operation to facilitate or complete the removal of diseased structures, and we must not then pause to consider whether with certainty the organs are irreparably damaged or not. It is safe to assume that, if hysterectomy is so necessitated, all the pelvic structures are deeply involved, and the preservation of the uterus is no longer a question of any moment; the organ is useless, or worse—a possible nidus of infection, and always a source of danger.

But these are the exceptions. The vaginal operation most frequently indicated in acute inflammation is incision and drainage, which from a surgical point of view is in no way to be compared with celiotomy or colpotomy with removal. It is a very simple procedure, and for this reason too much ignored amid the prevalence of successful laparotomy, but now that the suprapubic incision, with its brilliant result, has been tested to its fullest extent and its limitations have been found, we are more ready to recognize the benefits of the less impressive vaginal operation in its proper sphere. It is often the more correct surgical procedure, and the operator need no longer fear being accused of surgical timidity if he gives preference to incision and drainage over laparotomy when the mass is accessible, low in the pelvis.

The method has much in its favor. Relief is readily given without danger, and cure usually follows proper drainage with irrigation and packing, as in abscesses and acute suppurations in other parts. Even in earlier days before the time of successful laparotomy, when this was our only means of treating pelvic accumulations, very good results were achieved and many will remember the perforation with scissors and enlarging of the opening by sticking the blades or puncture with the trocar followed by dilators or forceps. By a timely use of the knife we may save much suffering, prevent peritonitis, and avoid the necessity of more serious operation at a later period.

If the result is a temporary one only, the patient will be in better condition for the following infra- or supra-pubic section.

For critical cases we rely upon vaginal incision. In the first stages of the disease we can successfully interfere by this method at a period when celiotomy would be unwarranted before fluctuation appeared.

Such is the valuable lesson taught us by Hentzen, who claims that 90 per cent. of pelvic inflammations may be cured by incision without extirpation if attempted in time. Dr. Harrington has emphasized this by the instructive pictures he has presented to us this evening of the phlegma of the hand and the advan-

stage of timely and free incision without awaiting the evidences of pus formation.

This may suffice to indicate how broad a field is open to the vaginal operation in acute pelvic inflammation. The advantage of the method is its general adaptability. It is conservative, simple and safe, thus justifying an early interference before indications for other procedures exist and enabling us to act when more serious or prolonged operations are inadmissible. These, too, give us the absolute indications for vaginal interference, as the high location of the tumor or the presence of peritonitis does for laparotomy; but beyond this distinct lines cannot be drawn, and the course to be followed must depend upon the safety of the method and the judgment of the practitioner, not upon his surgical inclination and preference.

The vaginal operation is not a surgically ideal one and cannot compare with the perfected abdominal section; but the question is as to the safest and most successful, not as to the nicest and most brilliant operation, and the broad-minded surgeon will adopt that which insures the best results with least danger to his patient. We must remember, too, in comparing the merits of the two methods, that these are not hospital cases which are given all the advantages of surgical skill and aseptic surroundings; they are acute cases which come to the practitioner or his consultant, and are treated in their homes, in city or country, where incision and drainage must always take precedence over laparotomy with removal of parts.

Dr. E. W. Cushing: The subject is divisible into two classes, both of which may be considered emergency cases: first, those described by Dr. Burrage, which are mostly post-puerperal or post-abortion, where there is great danger and something must be done right away. Now I think in those cases it is universally admitted that an abdominal operation is a grave one. In the first place, before the patient and friends have made up their minds, the happy time for interference is gone by; and if there is interference, there is such a mortality that it discredits surgery. If vaginal incision can be made early, you will strike one of two conditions. In the first class of cases, which is rare, you will find that, as a rule, the infection has spread through the tubes, and drainage can be obtained from the source of infection, which is the leaking of the tubes. You will see, if the abdominal operation is performed, that the fibrinated extremity is not closed. If a piece of gauze can be placed between the ends of the tubes so that all fluid is drained as fast as it comes out, the patient may be saved by simple drainage. In the second class of cases the inflammation is circumscribed and localized in the cul-de-sac or in the broad ligament.

I understood Dr. Reynolds's paper to refer more to cases with pelvic abscess, where an abscess has formed which ought to be opened; and the question is, How? Those cases where an abscess breaks into the vagina or rectum, often get well. The thought lies near to assist nature by opening, and especially to prevent rupture into the rectum by making an opening through the vagina; and ten years ago the best procedure seemed to be to puncture with an aspirating needle, and if you found pus to enlarge the opening with the thermo-cautery, and drain; and under this treatment the cases do very well indeed. Where the pus comes low down that can be done without ether. When we used to do that, it soon became evident that those cases were not all

in the cul-de-sac of Douglas, as was supposed; but we opened that space and found the collection of pus farther up. About that time came the great excitement about laparotomy; and, although we were successfully opening pus tubes from below with the trocar, there came then the apostles who persuaded us to do this work from above. Then it became evident that if anything more were done than to empty and drain the abscess cavity we would lose a patient operating from above who could have been saved operating from below. Given the fact that in grave cases it is not possible to do the full operation, and it becomes evident that if you can get to the source of pus from below and drain, you are getting all the advantages and few of the dangers; and this modern device of vaginal incision is applying with more correct surgery and modern principles what we used to do blindly. There are some cases where masses form high up, and perhaps the uterus is down, and the pus cannot be got at from the vagina without removing the uterus. Of those cases every one will have to judge for himself. In a severe case, where there is a considerable mass, where the patient is in pretty grave condition, and the pus high up, it may be desirable to sacrifice the uterus. You look then right into the pelvis, find the tubes, remove or open them and have free drainage. I think the method has a great application; and it is one of the most critical things for judgment and experience to know how to attack one of these abscesses where the symptoms are quite acute and the patient in a very grave condition.

Dr. REYNOLDS: Perhaps I ought to define what I meant by emergency operations. In the great majority of pelvic inflammations we wait until the attack is over, and then advise the patient to have a laparotomy done; in the minority we are obliged to operate during the attack. I meant to include all of these latter cases.

As regards the source of phlegmon, I think we ought to remember that there are a good many cases of phlegmon which result from exacerbations of an old, long-standing, pelvic cellulitis. In these cases the chronic lesion undoubtedly originated in the puerperium.—post-abortion or post-labor; but the acute attacks are excited by getting the feet wet, or by almost anything else. I am very sure it is not safe to leave that possibility out of view in dealing with cases which come to us without any question of recent labor or abortion. I have seen several cases during the last year even in which I felt very well satisfied that there was no question of recent labor or abortion, and which were yet cases of phlegmon. As regards puerperal sepsis, I have seen a great many puerperal cases. I have operated on some. I believe the prognosis of operation in a septic puerperal case is extremely bad anyway. When there is distinct encapsulation of pus I operate. I have saved a few perfectly hopeless-looking cases and lost a good many more. I think if we can save a few, we had better operate on them. It is very rare to save them after the symptoms of general peritonitis are present, and I have never saved one where the symptoms of general sepsis were present and due to streptococcus. Dr. Burrage spoke of using the enurette, even if it had been used by somebody else. I would always do it unless I knew that other man to be a skillful operator.

I would like to speak of one case before closing, because it is so exceptional, and shows that there is some

value sometimes in drainage in septic peritonitis. That was a case I saw in consultation, but did not operate on. Cesarean section had been advised, but she fell into the hands of a doctor who thought he could deliver through the pelvis at term. I saw her four or five days afterwards. She was propped up in bed, vomiting incessantly, gurgling green fluid from the mouth, with her abdomen as big as a barrel. They wanted me to do some operation, and I said I did not know of any operation. They insisted, and I said I would examine vaginally. I could not find any uterus or cervix, nothing but rags. Among the rags I found what I took to be a piece of the membranes; I pulled it out, and it was the omentum. The uterus had been torn away from the vaginal attachments. I thought the omentum had better go back; and I pushed it back as high as I could, behind the uterus. In the process there came away a pint of foul brown fluid, and it continued to drain. I told them there was no hope, and went away. Ten days later the husband came to thank me, and to say that his wife had not vomited since. Recently I saw her at my clinic at the City Hospital, in apparently perfect health.

CHONDRO-SARCOMA OF THE FEMUR.

DR. A. T. CABOT showed a specimen of chondrosarcoma of the lower end of the femur. The patient was a woman of between thirty-five and forty years, who a year ago began to have pains, believed to be rheumatic, in the left knee. Later, an enlargement of that joint was noticed and recognized as a new growth by her physician, Dr. Harris, of North Easton. A month before she entered the hospital she was etherized by Dr. F. G. Baleh, and a small bit of the femur was removed for diagnosis. Examination of this confirmed the existence of a sarcomatous growth in the bone. Amputation of the hip-joint was advised and accepted, and she entered the Massachusetts General Hospital for this operation.

Dr. Cabot operated by a rapid circular amputation just below the joint, removing the upper end of the bone after the vessels had been tied. The patient made a good recovery, and left the hospital at the end of about three weeks.

Dr. Cabot commented upon the very slight amount of shock caused by this operation under modern methods, a result which he ascribed to the avoidance of inflammatory irritation of this large wound quite as much as to the avoidance of hemorrhage.

AMERICAN ORTHOPEDIC ASSOCIATION.

ELEVENTH ANNUAL MEETING, WASHINGTON, D. C., MAY 4-6, 1897.

(Concluded from No. 6, p. 128.)

EXCISION OF HIP.

DR. W. R. TOWNSEND, of New York, read a paper with this title. He said that out of 2,295 cases of hip disease coming to the hospital, the joint was excised in 119. In 113 of these cases, it should be noted, there were more or less septic abscesses. No typical operation could be employed in these cases. No effort was made to close the wound and get primary union. Exhaustion was responsible for over 50 per cent. of the fatalities; meningitis caused 10 per cent. of the deaths, and shock was the cause in only nine cases.

The mortality-rate of this series of bad cases was about 52 per cent. Forty-seven patients were still living, and 26 had been cured of the disease. The patients' ages varied from three to fourteen years. Dr. Townsend favored amputation at the hip-joint in cases of extensive disease and severe sepsis, for this at once destroyed all the sepsis.

DR. DE FORREST WILLARD, of Philadelphia, said that we could not expect in this country to obtain the brilliant results of English surgeons, because it was our custom to operate comparatively late. Nevertheless, our plan of treatment was very useful, and he never despaired of saving a case by mechanical treatment until there was evidence of streptococcus or staphylococcus infection. When this occurred, he was in favor of excision. Dr. Willard then exhibited a skiagraph of a young man in whom he had performed excision with very satisfactory functional result.

DR. HERBERT L. BURRELL, of Boston, said that he had come to the conclusion that excision was indicated when the symptoms and physical signs showed that the patient was irremediably losing ground. He had recently seen a case in which, within ten days after the onset of the acute tubercular process in the head of the femur, he had felt called upon to make an incision into the joint and drain it. He felt sure that by this simple procedure he had saved the child from an ultimate excision, and possibly from something even more serious.

DR. JOHN RIDLON, of Chicago, said that he had seen two cases, in which, three or four years after excision, there had been a breaking down of the scar. He exhibited, in connection with this discussion, a skiagraph of a case in which, although there was undoubted and active disease of the hip-joint, the affected limb was larger than the healthy one on the other side.

DR. N. M. SHAFFER said that, in his opinion, excision of the hip-joint was rarely called for. If hospitals having the care of many of these children would provide a country branch, there would be still fewer excisions.

DR. SHERMAN said that the chief objections to early excision in children were the stunted growth of the limb, and, sometimes, the associated adduction. One of his recent excisions was a boy who was now able to ride a bicycle and enjoy himself as well as his companions.

DR. REGINALD H. SAYRE, of New York, said that while very few cases of hip-joint disease required excision, there were certainly some of these patients who had such feeble vitality that they could not rid themselves of the disease unless artificially aided in this way. He referred to one case in which by the removal of nine inches of the femur a far better result was obtained than could have been secured by amputation.

DR. LOVETT said that he fully appreciated the value of the climatic treatment, and many of the children who had been subjected to excision had had the benefits of a country hospital. Undoubtedly a few cases demanded early excision, as had been said; and it should be our effort to formulate the type requiring this exceptional treatment.

DR. TOWNSEND said that he had known the sinuses to re-open after excision, but this did not necessarily indicate a recurrence of the tuberculosis. It was probably due to a small piece of necrosed bone. He had known cases of even acetabular disease to be decidedly

improved by amputation, owing to the better drainage secured in this way.

THE PROGNOSIS OF HIP DISEASE UNDER EFFICIENT TREATMENT.

DR. LEROY W. HUBBARD, of New York, in a paper on this subject, stated that according to the best statistics from private practice—those of Dr. C. Fayette Taylor and Dr. L. A. Sayre—the mortality was approximately two per cent. A definite, positive prognosis in any given case was at present impossible; but there was a probability of recovery with little or no deformity, and with some motion in the joint, after careful mechanical treatment for at least two years.

GLUTEAL BURSITIS.

DR. E. G. BRACKETT, of Boston, read a paper on this subject. He said that in all these cases the limp was an early and persistent symptom, and differed from the ordinary limp of hip disease in not being subject to remissions. The pain was not very severe, was referred to the back of the leg and under the knee, and was not worse at night. There was some limitation of extreme flexion, particularly of flexion of the extended leg. Deep fluctuation could be detected in the upper part of the buttock. The bursa should be exposed by an incision a little to the inner side of the outer border of the gluteus maximus muscle. Usually a rather extensive dissection was necessary to completely remove the bursa. The wound should be packed, and the limb kept quiet for a few days.

DR. A. J. GILLETTE cited a case in which long after the cessation of a hip-joint disease, the patient developed much pain in the buttock, and along the sciatic nerve. On incising the abscess which was present, it was found to be in the bursa and to have no connection with the joint. The patient made a perfect recovery.

DR. E. H. BRADFORD, of Boston, presented

AN IMPROVED CLUB-FOOT SHOE.

He also made some remarks based on

A STUDY IN HUMAN GAIT.

He said that walkers could be divided into two classes, namely, (1) those who walk throwing the body forward; and (2) those who walk with the body straight. Fatigued troops, or persons carrying a load walk with the body leaning forward. Children strike the ground in walking, with the knee bent, using chiefly the front of the foot. In those toeing out and walking with a good deal of dignity, the tendency was to walk more with the heels. In a proper gait, the heel should strike first, and the leg should be straight when the weight falls upon it.

THIRD DAY, — THURSDAY.

TREATMENT OF DEFORMITIES OF THE KNEE RESULTING FROM TUMOR ALBUS, WITH ESPECIAL REFERENCE TO THE CASES IN WHICH THE PATELLA HAS BECOME ADHERENT.

DR. JOEL E. GOLDTHWAIT, of Boston, read a paper with this title. He said that when the patella was adherent to the end of the femur there was often as much as 30 or 40 degrees of motion, but, of course, without voluntary control in extension. The patella is situated almost always on the outer condyle of the femur, and obstructs extension as the tibia comes forward. In one of his early cases, having failed to re-

duce the deformity with the genuclast, he had opened the joint and removed the patella. Convalescence was very tedious, the joint remaining very sensitive for two years, and even after four years not being very firm. In the subsequent cases he had avoided the joint, doing the regular Macewen osteotomy well above the disease. After the reduction of the deformity the leg was put up in an extended position. In the cases so treated, convalescence was short and motion good.

DR. RIDLON said that in one case in which he had endeavored to reduce the deformity manually the soft parts in the popliteal region had been lacerated.

DR. A. J. GILLETTE said that, although he had operated seven times on these cases, it was only recently that he had observed paralysis subsequently. In that case there was loss of sensation below the knee.

DR. H. AUGUSTUS WILSON, Philadelphia, said that in his first use of the genuclast he had unintentionally fractured the femur a little above the condyles. Fortunately, this accident had enabled him to secure a position of hyper-extension.

DR. GIBNEY said that although he had not seen laceration of the soft parts follow forcible reduction of the deformity, he had found that in some cases, even under anesthesia, it was not possible to secure a good position. He had accordingly resorted to Macewen's subcutaneous osteotomy in a number of cases, and with the most gratifying results.

DR. GOLDTHWAIT, in closing the discussion, said that he always used the genuclast before resorting to osteotomy or other operation. He had not met with paralysis or fracture as a result of this practice. Where there was much cicatricial tissue in the popliteal region, the deformity should always be corrected gradually, in the course of several sittings. The machine used by him was a modification of Dr. Bradford's apparatus. The power is applied against the head of the tibia by a screw, the tibia being drawn forward before it is flexed.

GENERAL LAXITY OF THE LIGAMENTS, WITH CONGENITAL HIP LUXATION.

DR. HENRY LING TAYLOR, of New York, read a paper with this title, and reported two cases.

SKIAGRAPH OF CONGENITAL DISLOCATION OF HIP.

DR. JOHN RIDLON exhibited a skiagraph of such a case, from which it appeared that the neck of the femur on the dislocated side was straighter than the normal neck.

A FURTHER STUDY OF THE MECHANICAL TREATMENT OF UNUNITED FRACTURE OF THE NECK OF THE FEMUR.

DR. NEWTON M. SHAFFER, of New York, read a paper with this title. He reported three cases in addition to those that he had already placed on record, showing the results of his treatment of ununited fracture of the femur by means of a long hip-splint, surcingle and tourniquet over the fragments. This additional experience justified him, he thought, in urging the advantages of the method even more strongly than heretofore.

FOUR CASES OF RECENT FRACTURE OF THE NECK OF THE FEMUR.

DR. JOHN RIDLON read this paper. His treatment consisted in securing good approximation of the fragments, and then applying a Thomas splint, with adhesive plasters on both sides of the leg. These plasters are buckled to the ring, so that the limb was subjected

to constant traction, the amount being represented by the weight of the brace. In each of the cases the splint was removed in about eight weeks, and the union found to be good.

DR. R. H. SAYRE said he had found it rather difficult to use the tourniquet and to prevent the surcingle from slipping. In most cases it seemed to him necessary that the splint should pass above the pelvis in order to give a proper control over the fragments.

DR. A. J. STEELE said that sometimes the signs of fracture of the neck of the femur would not be present immediately after an injury, but would develop rather suddenly after some days. On several occasions he had found on the cadaver a thickening of the periosteum which accounted for the holding together of the fragments for a time.

DR. SHAFFER said that the surcingle in his apparatus should be cut so that it would nicely fit the pelvis; then it would not slip. Only very moderate pressure was to be made with the tourniquet, except when it was desired to move the patient in bed.

DR. RIDLON said that in these cases of recent fracture, he did not employ the shoulder-straps with the Thomas splint, and as the splint tended to slip down it made a certain amount of traction. The dressing was an exceedingly convenient one for use in private practice, for it allowed of the patient being moved about in bed with the greatest ease and safety, and it could be properly applied by the surgeon without skilled assistance. The bar of the Thomas splint should be at least one and a quarter inches broad. The Taylor splint allowed too much motion at the hip-joint.

COXA-VARA AS A MANIFESTATION OF LATE RICKETS.

DR. R. H. SAYRE reported a case of this kind, occurring in a girl of sixteen.

ADOLESCENT RICKETS.

DR. RIDLON reported a case occurring in a boy of twelve years. There was no history of tuberculosis or rickets in the family, and the boy was in good health up to the age of seven years, when he began to limp. A skiagraph of the hip showed the femoral neck destroyed, and the femur thickened about the trochanters. A skiagraph of the knee showed what appeared to be three epiphyseal lines.

GUNSHOT INJURIES OF THE TARSUS.

DR. J. D. GRIFFITHS, of Kansas City, presented a communication on gunshot injuries of the tarsus, and of other parts of the body. He had made an investigation of the effects in *actual field practice* of the modern 30-calibre gun with which our troops are now provided. He found that although the gun had been adopted in the belief that it was "a humane gun," it was far from being anything of the kind. At long range, with the regulation powder and ball, one shot striking a person just below the tibia was capable of shattering the greater part of the bone. The effect of such a shot on the foot was to grind the tarsal bones into small fragments. Specimens were presented in proof of these statements. He said that an effectual protection from these shots could be quickly extemporized out of loose earth.

DR. R. W. LOVETT, of Boston, was elected President of the Association, and Dr. John Rallou, of Chicago, Secretary for the ensuing year.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, AUGUST 12, 1897.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE RADICAL CURE OF INGUINAL HERNIA BY INJECTIONS OF CHLORIDE OF ZINC.

LANNELONGUE has reported the results thus far obtained of his treatment of hernia by the modified Heaton method, using for the material of the injection a ten-per-cent. solution of chloride of zinc.¹ He injects by means of a hypodermic syringe with a large barrel and long needle, twelve drops of the solution, making two injections at the same time, throwing the fluid well into the hernial canal, the internal abdominal ring being closed by the fingers of an assistant. The spermatic cord is kept out of the way as well as possible during the operation by the index finger of the assistant. The needle, as in the Heaton operation, is introduced through the outer ring well into the inguinal or femoral canal, and the mixture is injected as the needle is withdrawn by such a movement as will carry the point in various directions and bring the fluid in contact with the sides of the canal. A firm compress is applied, and the patient is kept in bed for a week or ten days, and must afterward wear a pad or light truss for some time. The operation is a painful one, and should be performed under ether. Out of 44 cases in young subjects, he claims 41 cures. Of the three cases reported as failures, one has subsequently been cured by a second operation of the same kind, the quantity of fluid injected the first time being insufficient. The other two cases were hernias of too large size to be permanently benefited by this operation.

It will be remembered that this mode of treatment is but an application of Lannelongue's "sclerogenous method," for which he claims great success in the treatment of cirroid aneurisms and tuberculous joints. The principle is the injection of some irritant mineral or vegetable substance which will provoke inflammatory thickenings, adhesions and the organization of new connective tissue. Nature often does this unass-

¹ Semaine Médicale, July 7, 1897; also July 8, 1896.

sisted in the lungs, and elsewhere, walling off bacilli, etc. In the inguinal canal which has become the seat of a hernia, and where a certain obliquity of the hernial tract still remains, the thickening and contraction of the walls and the new sclerotic tissue growth may completely occlude the passages by which the hernia was wont to descend, and the cure will be permanent. Unfortunately, although the exudations are considerable, the operation is not adapted to large hernias, and to cases where the obliquity of the canal has been destroyed. Nevertheless, even in these hernias, according to Weir,² the employment of the injection (Dr. Weir alludes to the Heaton injection of fluid extract of white-oak bark, which acts precisely as the chloride-of-zinc solution) "will so reduce the size of the canal as to permit better protection by a truss, and thus aid the individual in following his vocations." Weir has given this method a considerable trial, but is able to record only 12 cases out of 35 inguinal hernias. Bull and Gray report 9 cases out of 36 cases.

Whether Lannelongue's injection-fluid will prove more "sclerogenous" than Heaton's extract of oak bark, and thus be followed by a greater percentage of cases remains to be seen. It is probable that the zinc-chloride injection will prove to be more irritating, producing a denser fibrosis and firmer closure of the canal. These injections (whether Heaton's or Lannelongue's fluid be used) may be regarded as safe, if care be taken as to asepsis, and to exclude the liquid from the abdominal cavity. Heaton (who kept his method a secret for many years) emphasizes the importance of care and tact in making the injections. The injection should be begun when the needle is near the internal ring and should be deposited drop by drop in the cellular tissue of the inguinal canal "into the rings and around the sac" as the needle is gradually withdrawn from the external ring where it was inserted, the obliquity of the canal being observed and about twenty drops in all being inserted.

In view of the perfection to which operative methods of treatment have been brought of recent years, and of the excellent results which are now so widely attained by the operations of Bassini, Halsted and MacEwen, it seems hardly worth while to experiment with any procedure so blind and inaccurate as the injection of irritating fluids, especially when it has shown a definitely smaller percentage of cures. The mortality from operations for the radical cure of hernia in expert hands is *nil*, and it is generally admitted that in severe cases of inguinal hernia, namely, those in which the obliquity of the canal has been destroyed, and which cannot be held by a truss, operative measures afford the only prospect of relief, as here the injection treatment can offer no hope of success.

The argument that the injection method may find a place in the practice of country practitioners who would hesitate on account of lack of operative experience to perform cutting operations is a dangerous one; for practitioners, whether in the country or city, who

have had no special anatomical or surgical experience ought not to undertake the radical cure of hernia by the method of injection or any other method.

BERI-BERI AT THE RICHMOND ASYLUM, DUBLIN.

A NEW outbreak of beri-beri is reported at the Richmond Asylum in Dublin, where, as is well known to our readers, successive epidemics of the disease have appeared for several years. The serious nature of the outbreak is shown by the fact that 124 cases have already occurred, and its reappearance for several successive years in an English national institution, demands, as the *Lancet* remarks, careful consideration, and "the adoption with stringency of all such measures as experience has shown to be most likely to lead to good results."

The same paper further remarks:

The cause of beri-beri is unknown, for though all things point to a specific germ the exact organism has not yet been satisfactorily determined. The white staphylococcus of Pekelharing and Winkler, it is true, fulfils several of Koch's well-known postulates, which have to be satisfied by any germ claiming the honors of specificity, but the whole story has not yet been told. This is well shown by Dr. W. K. Hunter in a contribution to our knowledge of the etiology of the subject, which will be found on page 240 of this issue, [July 31, 1897] and which contains, in addition to a clear account of some careful experiments, an interesting *résumé* of the work of previous investigators. But although the discovery of a specific germ has yet to be made, we know perfectly well that where beri-beri has once broken out it is apt to remain, and also that overcrowding and bad ventilation are conditions which greatly favor its spread. In those Eastern countries where it is common it is a dweller on the threshold of gaols, and abides with communities where individuals live closely crowded together in defiance of health and decency. In addition to bad ventilation and overcrowding, it is also recognized that insufficient diet encourages the development of the disease. But it should be borne in mind that these conditions foster, but do not generate, beri-beri. The morbid entity which causes it must be imported into the locality in which the vicious environment prevails, an environment which is eminently favorable to the development of many other epidemic diseases.

That beri-beri was brought to the Richmond by patients, or in food or clothing from some Eastern country, is a well-nigh inevitable conclusion, but that its continuance there is favored by the conditions of life at the institution is also evident. Overcrowding and ill-ventilation must result from the facts stated by Sir Thornley Stoker, in a communication to a new Dublin paper, the *Daily Nation*, that "not only is the whole institution overcrowded far beyond its normal accommodation, but that even the new wooden male building is not fit to receive more than half the number at present occupying it. Its two dormitories are at present occupied by 100 patients, although not suited to give sanitary accommodation to more than 50. The female permanent hospital contains as many as 63 patients, who have an average of 451.968 cubic feet of space each." This space ought properly to suffice for the accommodation of 25 patients.

As the *Lancet* remarks, the persistency with which

² Transactions New York State Medical Society, 1887.

it clings to the unfortunate centre of infection is a repetition of what constantly occurs in its oriental homes.

After the drainage and ventilation, etc., have been properly provided for, something might be gained by investigating the diet of the patients, for it is well known that beri-beri, which was so prevalent in the Japanese navy as to threaten its efficiency, was entirely banished by the provision of a different and more liberal diet on board the men-of-war.

Beri-beri is not contagious from person to person, but it is so evident that buildings may become infected with it as to make it plain that the patients in any institution would be vastly better situated if removed to separate huts, well aired and drained, than if crowded together in the infected building.

The researches of Hunter go so far to confirm the results of Pekelbaring and Winkler, as to greatly increase the probability that beri-beri is due to a specific micro-organism, with which articles of food or clothing or habitations may become infected. If this be true, as it probably is, then the same conditions which tend to weaken the human organism, and render it susceptible to other microbic diseases, namely, unsanitary modes of life, insufficient diet, etc., ought and do increase its susceptibility to beri-beri.

MEDICAL NOTES.

THE NEW DIRECTOR OF THE BRITISH INSTITUTE OF PREVENTIVE MEDICINE.—At a recent meeting of the Council of the British Institute of Preventive Medicine, Dr. Allan Macfadyen was appointed Director of the Institute.

BERI-BERI AT CORK.—This disease has obtained admission to the port of Cork, having been imported thereto by the Norwegian barque *Hassell*, which arrived from the West Coast of Africa. Six of the crew are suffering from the disease and one has died.

APPENDICITIS AND BERRIES.—In Wayne County, N. Y., several cases of appendicitis which have occurred there have been attributed to berry seeds. Consequently berries are a drug in the market. Housewives refrain from preserving raspberries and blackberries, and farmers are forced to evaporate their berries or convert them into wine.

A TONSORIAL AUTO-DA-FÉ.—A lady recently lost her life in England by burns caused by the ignition of a petroleum hair-wash which a hairdresser was applying. It is not known how the spark was supplied, but the heat of the bright sunlight, the friction of the barber's hand on her hair and other possible though not very satisfactory causes have been suggested.

THE FOURTH FRENCH CONGRESS ON TUBERCULOSIS.—The fourth congress for the study of tuberculosis will be held at Paris during the last week of July, 1898, under the presidency of M. Nocard. The following four subjects are proposed for discussion:

"Sanitaria for Consumptives," "Serums and Toxins," "The X-Rays in Diagnosis and Treatment," and "Tuberculosis in the Lower Animals."

INFECTED RABBITS IN PARIS.—A number of rabbits which had been inoculated with cholera, diphtheria, plague and other diseases recently were stolen from their quarters at the temporary hospital at Aubervilliers in Paris. Considerable alarm at first prevailed on account of the fact that the animals had been stolen to be sold for food, but it is believed to have been calmed by the statements of bacteriologists that if the meat were well cooked, no ill results would ensue upon eating it.

VENEREAL DISEASE AMONGST THE INDIAN TROOPS.—In discussing the proposed proceedings in this regard of the Indian Government, Lord George Hamilton, as reported in the *British Medical Journal*, expressed the opinion that the inspection of soldiers, penal stoppages from admission to hospital, and the punishment of men concealing disease appear to be well calculated to check the spread of the mischief so seriously affecting the health of the British troops in India. He does not agree with the Government of India that the employment of female hospital assistants in the examination and treatment of women would be unnecessary and unsuitable. The system should be tried.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, August 11, 1897, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 39, scarlet fever 17, measles 11, typhoid fever 3.

DEATH OF A CENTENARIAN.—Mr. Michael Mallaly, the oldest resident of Roxbury, died recently. He was one hundred years old, and came to this country seventy years ago. He was a stone-mason, and served in Company K, Twenty-fourth Massachusetts Regiment, in the Civil War for three years.

NEW YORK.

BAD EFFECT OF RÖNTGEN RAYS.—Much public attention has lately been attracted to the case of a young woman who received injuries of considerable severity as the results of subjection to the Röntgen rays, by advice of her dentist. In commenting on it, Dr. William J. Morton, the electrical expert, has expressed the following opinion: "I reiterate my previous statements that the use of cathode rays by inexperienced persons is dangerous in the extreme. The tube should never be placed nearer than eighteen inches to the exposed surface, and the time of exposure is governed by the distance used by photographing."

A LOW MORTALITY.—The death-rate in the city is unusually low for the season, and it is not likely now that a mortality of one thousand will be reached in any one week during the present summer, as the largest number of deaths is almost always found to occur in the latter part of July or early in August. This year

the highest mortality thus far was reached in the week ending July 17th, when it amounted to 977. In the following week it declined to 920, and on the week ending July 31st, to 804; while during the week ending August 7th the total number of deaths was 795. During the last-named week there was but one death from sunstroke, and this was the first since the week ending July 17th. The number of deaths from diarrheal diseases has also been very small, 134 in the week ending August 7th, and 165 in the preceding week. There were 6 deaths from measles in the week ending August 7th, against 10 in the week previous, and 5 deaths from scarlet fever, against 8 in the week previous. In the two weeks the deaths from diphtheria were 21 and 22 respectively, and from typhoid fever 8 and 11 respectively. There has been no death from small-pox since the week ending July 24th, when there was one.

Miscellany.

NELSON AS A PATIENT.

An interesting account of Nelson's loyalty as a patient is published in the *Lancet* for July 24th, by Mr. Edmund Owen, F.R.C.S., who gives a facsimile of a letter written by Lord Nelson with his left hand on October 2, 1797, within ten weeks of the amputation of his right arm at Teneriffe, which was performed on July 24, 1797, just one hundred years ago.

As is well known, Nelson lost his arm in an attack on Santa Cruz made "with superb courage" by Nelson with about 200 men in open boats. While stepping out of the boat Nelson received a wound in the right arm, and fell. The principles of first aid were not entirely unknown at that time; for, as Southey says, a profuse hemorrhage which would undoubtedly have proved fatal was arrested by one of Nelson's officers, who bound some silk handkerchiefs tightly above the wound, while a boatman tore up his shirt to make a sling for the injured limb.

As soon as Nelson was aboard his ship again, he told the surgeon to get his instruments ready, for he knew that he must lose his arm, and the sooner it was off the better. Unfortunately, after the amputation the nerve, probably the median, was included in the silk ligature which secured the brachial artery, a fact which afterwards caused the hero intense and prolonged suffering. In those days, as is well known, the ends of ligatures were left long and were brought out of an angle of the wound to act as drains for the usual septic discharge; secondary hemorrhage was a not infrequent result of the too early removal of ligatures.

"Captain Mahan, in his 'Life of Nelson,'" writes Owen, "says that the ligature had been awkwardly applied. Nelson, however, did not say that the artery was 'awkwardly' secured. He was too loyal a patient to use such a word, and I do not believe that he ever thought it. He alluded to the inclusion of the nerve as an 'unlucky circumstance,' and when writing to his wife he said 'I am fortunate in having a good surgeon on board.' Certainly no surgeon would use the word 'awkwardly' in connection with the accident; it would be ungenerous and would suggest lack of dexterity on the part of the operator. Indeed, as

we look back upon that sorrowful early morning after the glorious failure at Teneriffe the surgeon of the *Theseus* receives a fair share of our kindly sympathy. He had no friendly help from ether or chloroform, and his patient was weak from loss of blood—not another drop must be lost. To day he would be prepared to supply such deficiency by the injection of a pint or more of hot salt water into a large vein. The amputation had to be done at lightning speed; as we know, the sea was rough, and we can imagine the scanty illumination below decks. Indeed, not only the field of operation, but the entire ship, must have been shrouded in gloom and depression.

"Returning to England, Nelson joined Lady Nelson at Bath, where he continued to be the subject of 'much pain and some fever.' For the ligature still held to the nerve, and the granulation-tissue lining the two-inch sinus was continuously absorbing small doses of the septic discharge. This auto-intoxication could not fail to make him ill and unhappy, and it probably caused him to be the subject of headaches, thirst, perspirations, and shiverings. Probably, also, this association of symptoms constituted the evidence of the 'fever' to which he alludes. Or, as there was no clinical thermometer in those days, the presence of fever may have been recognized by the mere application of the surgeon's hand to the surface of the patient's body—an extremely fallacious method of examination.

"A consultation was held in England as to whether the nerve could not be freed of the lingering ligature; but we learn that the surgeons were afraid to cut blindly into the depths of the sinus lest they should at the same time wound the artery with the scissors. So no interference was undertaken, and our hero was left to suffer. In similar circumstances, at the present time, the wound would be promptly and deliberately opened up and the removal of the ligature safely effected. But a hundred years ago surgeons were in constant dread of secondary hemorrhage from operation wounds—a contingency which aseptic surgery has practically abolished from our midst. They would not have dared to separate the adhering flaps of the stump lest, so doing, they might be courting disaster."

This letter, which is dated, "No. 140 Bond Street, October 2, 1797" and is perfectly legible, is as follows:

MY DEAR SIR:—I am much obliged to you for your kind enquiries. My arm from the unlucky circumstance of a nerve being taken up with the artery, is not yet healed, nor do I see any prospect of the ligatures soon coming away.

HORATIO NELSON.

As Owen remarks: "Whether in hospital work or in private practice soldiers and sailors make the best of patients. They give a willing obedience to all instructions, and they take things as they come, without question or complaint. Here was Nelson on October 2, 1797, in constant distress because a large uerve was by misadventure tied along with the artery, and speaking of its inclusion as an 'unfortunate circumstance.' *O si sic omnes!*"

TRIPLE GLANS.

DR. F. R. MILLARD, of San Diego, Cal., reports a case of this anomaly in the *Indian Lancet*.

The possessor of this anomaly, a healthy-looking German, unmarried, thirty-eight years old, weighing 175 pounds, applied for treatment of gonorrhea. The penis was small and the prepuce redundant. Retracting the prepuce a curious state of affairs was seen. The meatus was round and completely on the under side. The frenum was broad and formed a bridge under which a probe could be passed with ease. On the right side was a supernumerary glans one-third of

¹ Mahan: *The Life of Nelson*. London: Sampson Low & Co, 1897.

an inch from side to side, and one-fourth of an inch from before backward. At the junction of the inner and middle third was a linear depression, marking where the meatus should have been.

Entering a probe under the right border of the frenum and passing it on until the point was in line with this depression and then directing it backward it passed one and one-eighth inches parallel to the urethra to where the canal ended in a blind cul-de-sac. On the left of the frenum was another glans a little more than one-half as large as that on the right side, but it lacked both the linear depression for the meatus and the accessory urethra. Looked at from above and behind, it was an exact miniature of the main glans. Gonorrheal discharges exuded from both urethra, but there was no opening between them. The patient declined to enter into negotiation for sale of the specimen, nor would he allow a drawing to be made of it. His statement that all the deviations were congenital was undoubtedly correct.

Obituary.

DR. EUGENE F. SANGER.

DR. EUGENE F. SANGER, of Bangor, Me., died at that city on July 24th, after a long and honorable career as a physician.

Born in Waterville, Me., in 1829, he was graduated at Dartmouth College in 1849, and at Jefferson Medical College in 1853. Shortly after graduating, he was appointed assistant surgeon of the United States Marine Hospital at Chelsea, Mass., and in the same fall was appointed assistant physician and surgeon at the Charity Hospital and the various charitable institutions on Blackwell's Island, N. Y. After serving in the medical department of these institutions he pursued his professional studies and inquiries in the hospitals of Edinburgh, London and Paris.

In May, 1855, he settled in general practice in Ellsworth, Me., but soon removed to Bangor, where he continued to reside to the time of his death. On December 9, 1857, he was married to Emily Fay Pond, of Ellsworth, by whom he had three children.

During the Civil War he served first as a surgeon of volunteers, but soon was commissioned a brigade surgeon in the regular army by President Lincoln, and in January, 1863, was made medical director of the defenses of New Orleans.

An interesting anecdote of his courage and devotion to his duty is related in *The Bangor News*: When the Nineteenth Army Corps was reorganized for the famous Red River Campaign in January, 1864, Dr. Sanger was made medical director of the corps on General Franklin's staff. He took part in all of the skirmishes and battles, spending the subsequent nights operating upon the wounded.

"After the battle of Pleasant Hill, Dr. Sanger discovered at dawn that our forces had retreated during the early part of the night. Appointing an assistant to remain with the large number of wounded, he mounted a cavalry horse in pursuit. He overtook the head of the column over forty miles away. Securing an ambulance of supplies and an escort of a corporal and six privates, the next evening he crossed the enemy's picket line under fire, and, eluding the pursuit of the enemy under cover of darkness, appeared back at his hospital, forty miles distant, next morning. It was like an apparition to the deserted wounded. Meeting General Kirby Smith's medical director, Dr. Yandell of Louisville, the two completed the unfinished surgical work.

"Surgeon Sanger having collected letters from the captured soldiers to their families at home, as dark approached announced his intention of returning. Yandell said, 'They

will surely shoot you.' Notwithstanding the danger, the doctor retraced his steps through the rebel army, and found himself near the Union picket line next morning."

On August 6th Surgeon Sanger was assigned to duty at Elmira, N. Y., in medical charge of the barracks for Confederate prisoners to the number of 9,000 to 10,000, where he remained until the latter part of December, when he, at his own request, was relieved by the surgeon-general of the United States Army, because he found it impossible to do justice to the sick prisoners, on account of the military interference with the proper management of so large a number of prisoners herded together in an ill-selected enclosure.

After Elmira, Surgeon Sanger reported to General Hooker, and was made medical director of the District of Michigan, and surgeon-in-charge of Harper's and St. Mary's Hospitals in Detroit. Subsequently he reported to General Thomas at Nashville, and was assigned for duty at Knoxville and Chatanooga as medical director of the District of East Tennessee, where he remained until mustered out of the service in September, 1865. He was brevetted lieutenant-colonel for meritorious service.

Returning to Bangor, he commenced the practice of his profession in October, 1865, and continued to the time of his death. He was made surgeon-general of Maine under Governor Chamberlain's administration, and served seven years as surgeon of the Second Regiment of the State Militia. He was a member of the common council in 1870-71, and was president of the Maine Medical Association in 1876. He was an honorary member of the Detroit Academy of Medicine, and of the Baltimore Medical and Surgical Society; a member of the county, State and national medical associations.

Dr. Sanger had a very large surgical practice and contributed numerous papers to medical journals and to the "Transactions of the Maine Medical Association."

Before the time of hospitals in Maine, and when the railroad service was limited, it was no uncommon thing for a doctor to ride all night to attend a single surgical case. He hesitated at nothing in surgery—from the removal of cataract, amputation, tracheotomy, laparotomy, aneurisms, stone in bladder, to the correction of all kinds of deformities.

On November 19, 1890, he married for his second wife Mary R. Treat, a granddaughter of Major Treat, a Revolutionary officer.

One of his sons, Sabin P., is a banker in Boston, while the other, Eugene B., who is a graduate of Yale, Class of 1891, and of the College of Physicians and Surgeons, New York, 1894, is a successful physician in Bangor, for some time past associated professionally with his father.

A FAITHFUL NURSE.

Miss ROSA MCCORMICK began her services as nurse at the Boston City Hospital in 1864, and remained on active duty until 1892, doing twenty-eight years of continuous nursing. During most of this time she was in full charge of a ward of thirty beds. Such a career is exceptional, and worthy of comment.

All those who have been connected with the hospital will recall her comely and cheerful presence. She was always prompt and conscientious and kind, although, also, a good disciplinarian.

In later years Miss Rosa was the type of a senior and retired nurse, beloved and respected by all, and doing a nominal duty at the Convalescent Home of the City Hospital.

The Hospital authorities dealt more kindly with her than did time, for she died on August 1st, at sixty-five years of age, worn out, and of much greater apparent age.

Those who give themselves for others who are sick, whether nurses or doctors, relinquish much peace of mind, and also usually shorten their lives. Their reward is elsewhere; and we fear not that it will be justly meted out to this faithful nurse.

METEOROLOGICAL RECORD

For the week ending July 31st, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Date.	Baro. meter.	Thermom- eter.	Relative humidity.	Direction of wind.	Velocity of wind.	Wet't'r.	Rainfall in inches.
	Daily mean.	Daily mean.	Maximum. Minimum.				
			8.00 A. M. 8.00 P. M.				
S. 25	29.85	67 72	73 92	N.	E.	12	0.0
M. 26	30.08	62 65	65 73	N.E.	N.E.	14	0.0
T. 27	30.12	59 63	63 84	N.E.	E.	15	0.0

Deaths reported 3,710; under five years of age 1,930; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping cough, erysipelas, and fever) 1,141, diarrheal diseases 916, consumption 254, acute lung diseases 184, diphtheria and croup 86, typhoid fever 53, whooping-cough 31, scarlet fever 19, cerebro-spinal meningitis 18, measles 15, erysipelas 3.

From whooping-cough Washington 8, New York and Philadelphia 5 each, Brooklyn 4, Chicago 3, Cincinnati and Providence 2 each, Cleveland and Everett 1 each. From scarlet fever New York 8, Brooklyn 4, Philadelphia 3, Chicago, Baltimore, Boston and Springfield 1 each. From cerebro-spinal meningitis New York 7, Boston and Washington 4 each, Cleveland, Lynn and Malden 1 each. From measles New York 10, Brooklyn 2, Chicago, Philadelphia and Lowell 1 each. From erysipelas Chicago 3.

In the thirty-three greater towns of England and Wales with an estimated population of 10,992,524, for the week ending July 24th, the death-rate was 19.3. Deaths reported 4,060; diarrhea 526, measles 153, whooping-cough 92, diphtheria 60, scarlet fever 48, fever 25.

The death-rates ranged from 10.1 in Derby to 26.4 in Liverpool; Birmingham 22.5, Bradford 13.1, Cardiff 13.8, Halifax 10.9, Leeds 18.1, Leicester 18.7, London 20.0, Manchester 19.8, Newcastle-on-Tyne 14.9, Nottingham 19.5, Portsmouth 20.8, Sheffield 25.3, West Ham 17.9.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 31, 1897, TO AUGUST 6, 1897.

MAJOR PAUL R. BROWN, surgeon, having been found by an Army Retiring Board permanently incapacitated for active service, will proceed to his home and await retirement.

The order directing MAJOR PAUL R. BROWN, surgeon, to report for duty at Fort Keogh, Mont., upon being relieved from duty at Fort Hamilton, N. Y., is revoked.

CAPTAIN WILLIAM B. BANISTER, assistant surgeon, is relieved from duty at Fort Crook, Neb., and ordered to Fort Keogh, Mont., for duty.

Leave of absence for one month and ten days, to take effect on or about August 20, 1897, is granted LIEUT.-COL. ALFRED A. WOODHULL, deputy surgeon-general, chief surgeon, Hdqrs. Department of the Colorado.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE WEEK ENDING JULY 31, 1897.

KINYOUN, J. J., passed assistant surgeon. Designated as delegate to represent the United States at the International Conference relating to Hygiene and Sanitary Service on Ship-board and Railways, to be held at Brussels, Belgium. July 29, 1897. Also designated as delegate to represent the United States at the International Conference to discuss the Leprosy question, to be held at Berlin, Prussia. July 29, 1897.

RECENT DEATHS.

GEORGE WEBB WEST, M.D., M.M.S.S., died at Chestnut Hill, Newton, August 5, 1897, aged forty-seven years.

SIR JOHN BUCKNELL, F.R.S., the author of important contributions to neurology and insanity, formerly editor of the *Journal of Mental Science* and one of the editors of *Brain* and of the *British Medical Journal*, died at Bournemouth on July 20th, aged seventy-nine years.

PROF. OSCAR BOER, of Berlin, known for his work on infectious diseases, has recently died in that city.

PROF. JOHANN RITTER VON LEICH, formerly dean of the medical faculty of the University of Vienna, died recently at the age of eighty-four.

PROF. M. J. OERTEL, the distinguished laryngologist, died on July 13th in Munich, aged sixty-two.

CASE OF TEMPORO-SPHENOIDAL TUMOR, PRESENTING SYMPTOMS SUGGESTIVE OF ABSCESS.

BY W. L. RICHARDSON, M.D.,

Visiting Physician, Massachusetts General Hospital;

AND G. L. WALTON, M.D.,

Physician to Neurological Department, Massachusetts General Hospital.

THE patient, a prominent business man, sixty-nine years of age, of unusual intelligence and executive ability and of genial disposition, showed slight signs of mental change for six months or more preceding his death. It was noticed, for example, that it was difficult for him to keep his mind upon any continued line of thought. He would repeat anecdotes to the same listeners and find difficulty in telling them correctly. It was also noticed that the patient, though clear in many matters, for example, financial affairs—and, if anything, more interested in details than formerly—in some ways would show inattention. He would sometimes fail to notice when others were talking, and would interrupt them. He was at times inclined to be more talkative than usual, and more persistent in having his own way. It was noticed during the summer preceding his final illness, that during a trip he would form his own plans and would not vary from them, whereas his natural tendency was to ask others what they would like to do, and make plans with reference to their convenience. He would repeat himself in conversation. His disposition gradually changed during this time, and towards the end he would sometimes speak quite sharply. Sometimes he became quite loquacious and inconsequential; for instance, on being asked how he felt, would answer, "First rate, great a, little a, bouncing b," etc. Towards the end he suffered from very marked lapses of memory, forgetting from day to day what he had done. There was throughout no disturbance in articulation nor trouble in choosing words. With these changes he maintained almost to the end a bright and even jocose manner of answering questions, especially when under the excitement of the physician's visit.

The patient had suffered for several years from an inflammation of the middle ear, with pain and discharge, an accurate description of which trouble is furnished by Dr. Blake, whose report is appended.

REPORT OF AURAL CONDITION (DR. BLAKE).

I first saw the patient professionally in October, 1890, on account of an impairment of hearing in the left ear, due to the closure of the Eustachian tube consequent upon a head cold, which was easily relieved by the usual treatment. For many years, almost since he could remember, this left ear had been his main dependence for hearing purposes, the hearing of the right ear having been seriously impaired as the result of a suppurative inflammation of the middle ear in childhood.

Examination of the right ear at that time showed a large perforation, very nearly a destruction of the membrana tympani, the long process of the malleus being indrawn by contraction of the tensor tympani muscle until the tip of the bone touched the promontory to which it had become attached by cicatricial growth; a tense and firm cicatrix also extended from the upper border of the old perforation, both in front of and behind the malleus, down upon the promontory; and still other cicatricial bands below served to enclose that portion of the inner tympanic wall directly in view. Hearing tests showed a very marked impairment of hearing for sounds aërially conveyed.

During the interval between this examination and his last illness, he had several slight attacks with trouble in the left ear which brought him under observation, on which occasional inspection of the right ear showed it to remain unchanged, both as to appearance and as to hearing power, as was also the case during his last illness, with exception of a slight congestion of the blood-vessels in the upper remaining portion of the membrana tympani and at the extreme inner end of the upper wall of the external auditory canal; but while this reddening suggested a congestion in the epi-tympanic space, it was too slight in degree to be taken as an evidence of any serious trouble.

About seven weeks before his death he complained for the first time of headache on the right side over the ear, but was out and about; and on Thanksgiving Day (a month before his death) he went out of town to dinner, and appeared very well. On the following day he became quite weak, walked very slowly; and on the second day after Thanksgiving he became so feeble that he had to be supported. That day he took to his bed, which he did not leave, except to be assisted to an easy-chair. From this time on he could hardly roll over or rise in bed without assistance.

Physical examination two days after Thanksgiving showed extreme general weakness, with marked impairment of the movements of the left leg. On being asked to raise the foot so as to touch an object with the toe, he did this fairly well and promptly with the right toe, but with the left toe in a very weak and uncertain manner. He answered questions at this time correctly, but appeared on the whole somewhat sluggish and apathetic, though he was still inclined to answer simple questions in a jocose manner. The pulse was 80, full and soft, the arteries were markedly atheromatous. There was inability to distinguish objects to the left of the median line in each eye (left hemianopsia).

The patient writes, "God save the Commonwealth of Massachusetts" in a good hand without a mistake. Examination of the fundus unsatisfactory on account of patient persistently looking down, trying to close eyes and showing distress generally.

No material change appeared in the patient's condition during the next few weeks, except that the mental condition became decidedly worse and conversation at times rambling and incoherent. He could, however, at any time be brought to himself by a sharp question. Temperature and pulse were practically normal until within forty-eight hours of his death. An examination of the urine by Prof. E. S. Wood showed early in November only a concentrated condition with excessive acidity and a slight renal irritation. This condition disappeared under the use of mild alkaline diuretics. At times headache appeared severe enough to interfere with sleep, but this symptom was on the whole not prominent. No vomiting occurred throughout.

Second examination of the field of vision, on the 2d of December, showed that the patient distinguished blue, red and yellow at a normal distance in the proper order on the right with each eye, but did not distinguish them on the left until they reached the median line. At this time the grasp of the left hand was extremely feeble, that of the right good. Objects were taken up easily with the right hand, but with the left were taken up feebly and with fumbling. The left leg was much weaker than the right, and in attempting to walk the patient would put the right foot forward and bring the left up to it. No facial paralysis appeared.

The knee-jerks were normal and alike, the pupils alike and reacted to light. The movements of the eyes were unimpaired. Examination of fundus again unsatisfactory, on account of patient's inability to fix.

From this time the patient gradually lost ground, completely losing the use of the left leg, and practically that of the left arm. His memory became so greatly impaired that he would say that he had eaten nothing directly after taking his nourishment. On the day before Christmas the pulse and temperature rose steadily, the patient became comatose, and died quietly Christmas morning. The autopsy was made by Dr. W. F. Whitney, whose report is appended:

Autopsy, December 25, 1896, at 11.30 A. M., five hours after death. Body of an old man of large frame. Rigor mortis present.

Head.—The calvaria was dense, but with two smooth depressions close to the median line in the parietal region, due to senile atrophy. Inner surface normal, dura slightly adherent.

The right hemisphere more prominent than the left, and the convolutions slightly flattened. On attempting to remove the brain it was found to be adherent to the dura mater covering the anterior part of the right middle fossa, opposite the temporal lobe, from which projected a new growth. Section showed this to be a soft mass, ill defined from the rest of the brain substance, measuring about six centimetres by four centimetres. It occupied the first two temporal convolutions in this region and extended back into the white substance, where there was a recent hemorrhagic infiltration the size of a large cherry. The appearance of the growth was quite like that of the gray substance of the brain, but more translucent, less firm and marked by hemorrhages.

Microscopic examination showed its structure to be made up of numerous small cells, many of them with irregular fine prolongations, the whole forming a finely-felted mass. On this were numerous small, newly-formed blood-vessels and large polynuclear cells, some of a pear shape with a single large protoplasmic prolongation suggesting ganglion cells.

Elsewhere the brain was normal, and there was no evidence of any direct implication of the optic tract on the right side.

Diagnosis.—Small-cell glioma of the brain, originating in the two first temporal convolutions of the right side, with a recent hemorrhage into its substance.

The chief interest in this case lies in the remarkable coincidence that a glioma, whose origin was, of course, entirely independent of the ear, should appear in the exact location usually occupied by cerebral abscess arising from aural infection. The coincidence becomes even more remarkable when we realize that the tumor was not only seated on the under surface of the temporo-sphenoidal lobe, but that it occupied this lobe on the side of an old, purulent, middle-ear trouble. It is true that the discharge had long since ceased, that no sign of active inflammation existed, and that exploration of the tegmentum tympani by Dr. Blake showed no direct extension of infection; this, however, by no means precluded the existence of an abscess, for this lesion not only follows direct extension from inflammation of the tympanic cavity or the mastoid, but also from infectious thrombosis. In fact, such abscesses are produced by this mechanism in various parts of the brain, even on the opposite side from that of the affected ear. Such a case has recently been described to us by Dr. Crockett. In this case the patient, who had suffered from a chronic middle-ear trouble of long

standing, but with no discharge for many years, was admitted to the Eye and Ear Infirmary for vague cerebral symptoms, such as apathy and change in disposition and moderate headache but with no localizing signs. The autopsy revealed an abscess in the frontal lobe with no line of communication to the ear. It is a well-known fact that similar abscesses deeply seated in the brain have been revealed by post-mortem examination, though no sign of their presence existed during life. It is true that this variety of abscess is far less common as result of aural infection than the form resulting from direct extension and appearing during a comparatively acute stage of middle-ear inflammation.

An abscess set up by this means may become chronic, gradually increase in size and give rise to alarming symptoms, only when so extensive as to encroach upon the important nerve tracts. It must be remembered in this connection that abscesses are less prone than tumors to produce symptoms by pressure beyond the limits of the diseased tissue. The altered mental condition noticed in this patient in the course of the year preceding his death is consistent with both tumor and abscess; but the lack of attention, the loss of that consideration for others and deference to their wishes previously characteristic of the patient, the lack of ability to carry out extended lines of thought, and the lapses of memory running into delirium without marked headache or vomiting, in the case of a person with either present or past purulent middle-ear trouble would certainly primarily suggest abscess. When such symptoms are followed by sudden accession of weakness, mental and physical, with loss of flesh and rapid onset of hemiplegia and hemianopsia, with no vomiting and with comparatively little headache, a presumption would naturally be established in favor of abscess, which had reached the optic tract and internal capsule by direct extension, rather than of tumor which had produced these symptoms indirectly by pressure, though the possibility of tumor in such circumstances could certainly not be denied. The irregularity and range of temperature again (from 97° to 99°) would strongly suggest abscess. The only arguments for tumor were too inconsiderable to turn the balance, namely, the absence of chills and the age of the patient. Tumor is certainly more frequent in advanced life than abscess, still the latter may occur at any period. The presence or absence of optic neuritis might have aided in the diagnosis, though its presence would not absolutely have established the diagnosis of tumor, as this symptom is sometimes present in abscess also; in fact, Gowers considers this symptom much more common than published reports would indicate.

Two attempts to examine the disc were made unsuccessfully, the patient being absolutely unable to fix the eye, and showing such signs of distress that the attempt was abandoned. If the decision of this point had been deemed in any way essential to the patient's relief, the assistance of one more skilled in ophthalmological examination would have been sought; the location of the lesion was, however, absolutely established, and operation decided against in either event.

The question of operation was very carefully considered in all its aspects, the conclusion being reached, in view of the patient's senility (as evidenced, for example, by the marked and extensive atheromatous arteries) and the depth of the lesion, that the patient's condition would be probably made worse rather than better by operative interference. The family were

very naturally opposed to operation on such a discouraging report as we were forced to give them, and to the patient the subject was never broached.

The autopsy certainly established the uselessness of operative interference, as the removal of the tumor would have involved practically the removal of a very

FIG. I. Showing seat of tumor.

considerable portion of the temporo-sphenoidal lobe, as will appear from the accompanying cut. If attempted, the operation would probably have resulted in an extensive brain hernia, with its attending inconveniences and discomforts, thereby increasing rather than diminishing the patient's distress.

FIG. II. Diagram showing order of involvement of leg, arm, and face fibres by lesions of the temporo-sphenoidal lobe (Macewen).

The most interesting point in connection with cerebral localization is that of the order in which the limbs were affected, a point upon which Macewen lays much stress. In case the lesion extends along the surface of the brain from the temporal lobe, involving successively the Rolandic areas from below upwards, the paralysis begins with the face, and the arm and leg become successively involved. If, on the other hand, the process extends inward and encroaches upon the internal capsule, this order is reversed, because the

fibres from the leg and arm centres cross before reaching the internal capsule.

A glance at the diagram used by Macewen² (Fig. II) will make this point clear. A practical application of this knowledge bears on the question of operative interference. In case we have to do with an abscess, paralysis commencing with the leg tends to show that the lesion is very deeply seated, though it is true that abscesses sometimes cause symptoms by indirect pressure, as shown by the improvement after evacuation of their contents. In the case of tumors, the involvement of more or less remote regions by pressure is quite characteristic, as evidenced by the case here reported, in which the order of paralysis indicated pressure upon the internal capsule, although the post-mortem examination showed that the tumor had not itself invaded that region. Nor had the tumor directly invaded the optic tract, though the marked hemianopsia showed pressure upon that tract, posteriorly to the optic commissure.

This unique case, while offering an excellent illustration of the present status of cerebral localization, only emphasizes the difficulty of determining the exact nature of hidden lesions.

RUPTURES OF THE VISCERA AND THEIR CONNECTION WITH SURGICAL SHOCK.¹

BY EDWIN WELLES DWIGHT, M.D.,

Surgeon to Out-patients, Boston City Hospital; Assistant in Legal Medicine and Clinical Surgery, Harvard Medical School.

AFTER accidents of a certain degree of severity, the following group of symptoms is usually found; and when there is no external or known condition to account for them they are taken together and called "shock." These symptoms are lowered temperature, rapid pulse, sighing respiration, restlessness, and cold moist skin; and it is to this group of symptoms rather than to any lesion that the term "shock" is applied. The same symptoms are found with hemorrhage; and it is only when the question of hemorrhage has been eliminated that this term is used.

Shock is being constantly presented to the surgeon in all stages of severity up to the most profound collapse; but it is only in its more severe forms that it is apt to be seriously considered as an obstacle to the radical treatment of the more definite lesion for which treatment is requested. While there are cases in which even the autopsy fails, as yet, to demonstrate the actual lesion which caused death, they are very rare; and there can be little doubt that in the future, with increased accuracy in diagnosis, the word "shock" will, as has already been the case with those equally indefinite terms "idiopathic peritonitis," "scrofula" and "inflammation of the bowels," be superseded by diagnoses more in accord with scientific accuracy, and which will give some idea of the lesions underlying this group of symptoms. It is especially true after severe accidents that the autopsy almost invariably develops some condition which is sufficient in itself to account for the death, and that after an autopsy it is rarely, if ever, necessary to use vague terms to account for it.

¹ Read before the Boston Society for Medical Improvement, March 22, 1897.

² Macewen: Diseases of Brain and Spinal Cord, p. 152.

In a "Report of One Hundred and Sixty-nine Autopsies in which a Fracture of the Skull was Found," published in 1894, I found but two in which there was not found some lesion which would readily account for the death; and the statement was made that, "In railroad and electric-car accidents, where shock is most often given as the direct cause of death, all the autopsies showed lesions in themselves sufficient to account for it. In ten of these cases there were 'multiple injuries' found, which had not been suspected during life, but which were the direct cause of the condition which had been considered as shock, as well as the cause of the patient's death."

Not only is this true of railroad injuries, but of all other deaths from external violence; and if it be true of shock in its more severe forms, is it not reasonable to suppose that the milder grades are caused by similar conditions, but of less severity?

My presence, through the courtesy of Dr. F. W. Draper, at a rather large number of medico-legal autopsies, as well as at those made in the ordinary work of the hospital, has led me to believe that not only are ruptures of the viscera more common than is generally supposed, but that these ruptures vary within wide limits in their severity; and that it is at least possible that in many of the cases of so-called "shock," the symptoms are due, not to any indefinite jarring of the nervous system, but to hemorrhage from ruptured organs. That these ruptures do occur in all of the viscera, in all grades of severity, and after a variety of common accidents, I believe the cases reported with this paper show; as they also do that in autopsies where ruptures of the viscera are found, death occurs, not from "shock," but from some more definite cause, usually hemorrhage or peritonitis.

Injuries to the abdomen in which no exact diagnosis is made clinically are of very common occurrence in our hospital wards; they occur after a great variety of accidents, but most commonly from assaults or falls of various kinds. Bryant, in his "Practice of Surgery," speaks of 71 cases of "abdominal injuries" which were admitted to Guy's Hospital in eight consecutive years, and says: "In 44, beyond a passing collapse, no serious or definite symptoms resulted, tenderness over the injured part from the contusion being the most marked; but no evidence of internal mischief showed itself; rest in bed for a few days was the chief treatment, and convalescence rapidly was established. . . . In 10 cases peritonitis followed, with nausea and some vomiting; in seven of these it did not attain a dangerous degree of severity; in three it was severe; and one died. In 17 cases, or about one-fourth, rupture of the viscera took place."

From the records of the Boston City Hospital I find that during the past fifteen years there have been 79 cases of abdominal injuries, more or less localized, admitted, in which the diagnosis of rupture has not been made, and in which no definite lesion was found to account for the symptoms which were present. These cases are catalogued under two heads, "Contusions of the Abdomen" and "Traumatic Peritonitis"; of these, 16 died. In 68 the character of the accidents was such as commonly results in rupture, that is, they were falls from a considerable height, run over by wagons of various kinds, or assaults in which the victim received a number of blows or kicks. "Shock" was present to a noticeable degree in 49. Rupture

of the viscera was seriously considered in 14, but the diagnosis was not made. Tenderness on deep pressure, persisting for from four to sixteen days was noted in 39, and persistent vomiting existed in the same number. In none of these cases was an autopsy made; and it will be noticed that in quite a large percentage, not only was the accident such as frequently causes rupture of the viscera, but the symptoms which are usually found in such conditions were present. Still another class of cases in which the diagnosis is indefinite, and when applied to the seriously injured usually means that the apparent injuries do not adequately account for the symptoms which are present, are those which are grouped under the head of "Multiple Injuries." During the same fifteen years there have been 81 cases of serious "multiple injuries," exclusive of those in which the skull has been known to be fractured, 36 of which died within three days. No autopsy was made in these cases, and "shock" was pronounced in every one.

The amount of "shock" present after accidents depends upon two factors, the character of the violence, and the resistance of the individual; being most marked after those injuries which are most apt to result in ruptures of the viscera, and in those persons whose resistance, through age or disease, is lowered.

In order to show the conditions which cause death in ordinary accident cases I have chosen three very common results of ordinary accidents: fractures of the ribs, which usually result from crushing force, severe falls or assaults, and in which "shock" is frequently noticed; fracture of the femur, commonly occurring in elderly people from falls of moderate severity, and with which "shock" is not infrequently associated; and simple fractures of both bones of the leg, which are commonly the result of direct violence or falls on the street. The cases taken were admitted to the Boston City Hospital during the fifteen years from January, 1882, to January, 1897.

Of fracture of the ribs 511 cases were admitted, with 40 deaths; 29 dying within three days. There were nine autopsies; three died from pneumonia, three from hemorrhage from ruptures of the lungs, and three from ruptures of the liver and spleen.

There were 885 fractures of the femur, with 102 deaths; of the 23 who died within three days there were three autopsies: one from the general arteriosclerosis, with plugging of the coronary artery; one from the same disease with a weak heart and edema of the lungs; and one from rupture of the kidney. There were 79 who died after three days with 15 autopsies, which resulted as follows: pneumonia, four; delirium tremens, with passive congestion and edema of the lungs, three; arterio sclerosis with weak heart and edema of the lungs, six; organic disease of the heart, one; pulmonary embolus from thrombosis of the femoral vein, one.

Of fracture of both bones of the leg there were 975, with 18 deaths. Four died within three days, with one autopsy, in which death was due to rupture of the lung; the three in which no autopsy was made were clinically complicated by "burns," "fracture of the spine" and "injury to the abdomen" respectively. On those who died after three days there were six autopsies: delirium tremens, with edema of the lungs, three; pneumonia, two; and multiple fat emboli, one.

The autopsies on these cases show that in the fractures of the ribs where the violence is of the character

which might be expected to produce such conditions, death was due in two-thirds of the cases to ruptures of the viscera; and in the other third it is fair to assume that the exciting cause of the pneumonia was injury to the lung. In fractures of the femur, where the resistance is commonly lowered by age or habits, death was the result of those conditions in every case but two, in one of which it followed rupture of the kidney, and in the other pulmonary embolus; while in fractures of both bones of the leg where the conditions are more variable, there was one of rupture of the lung, five from intercurrent disease, and one from fat emboli.

Ruptures of single organs without involvement of others appear rather rarely at the autopsy; and when but one organ is involved and death ensues rapidly, the only cases that I have been able to discover in which there had not been hemorrhage enough to account for the death, or in which peritonitis or pneumonia was not the active agent, have been those of ruptures of the heart and aorta.

The time elapsing between the accident and death varies from a few minutes to several days; and in a few instances life may be prolonged for weeks, the duration of life being, almost without exception, in inverse proportion to the amount of blood which was lost.

The influence of nerve shock does not seem to enter into these cases, although it is possible that in very rare instances death may be due directly to the effect which blows upon the abdomen have upon the sympathetic nerves. The cases which have been reported in defence of this theory are very unsatisfactory, and usually, like the historical one of which most authors since Sir Astley Cooper speak, are from hearsay rather than direct evidence. The multiple character of fractures of the organs in these cases may be accounted for in various ways; it would seem, however, that in a number of them it was due to the character of the injuries received, which in the majority of cases were of such a nature that it is fair to assume that the blows were also multiple.

The amount of injury to the various organs varies greatly as does the amount of hemorrhage; and we find all degrees from a slight contusion to complete rupture or maceration, as we do from small ecchymoses to the extravasation of several pints of blood. As the injury and the amount of hemorrhage vary so widely, and as the duration of life in those cases which come to autopsy depends upon these factors, it is evident that the symptoms in cases of less severity, depending as they do upon the same conditions, must be at least as variable.

The diagnosis of these conditions during life is further hindered by the fact, which has long been recognized by medical jurists, that ruptures of the viscera are the common results of accidents which leave no external sign. Caspar, than whom there have been few better observers, makes this rather radical statement in his "Hand-book of Forensic Medicine": "That it is the rule in all such cases as are followed by instant or very sudden death, particularly in all cases of rupture of the internal organs rapidly fatal from internal hemorrhage, for the body to exhibit no external appearance of external violence. This experience has often enabled us to diagnose the rupture of some important organ, in the case of men falling from a height, or being driven over, etc., just because no sign of in-

jury was to be found externally; and our opinion has been proved correct in every case."

Not only are external bruises absent in many, if not in the majority of these cases, but other symptoms which might be expected to be present in injuries of the various organs are frequently absent, even where life is prolonged for days or weeks. If this be the case with severe forms, how much more likely they are to be absent in the lighter forms of injury.

Ruptures may take place in any part of any organ; and while death may occur almost instantly in some, in others life may be prolonged, and death result from entirely secondary causes, as peritonitis, pneumonia or secondary hemorrhage; and in still others the laceration may entirely heal and perfect recovery take place.

Opinion as to the relative frequency of rupture of the various viscera varies much with different observers. Caspar, after speaking of rupture of the liver, says, "With the exception of rupture of the uterus during labor and rupture of the spleen, which when they do occur are usually transverse, rupture of the other abdominal organs is almost never observed." Bryant says that the spleen is frequently injured, and "Such cases are by no means always fatal," and again, "Rupture of the kidney is an accident from which recovery is more common than from any other viscus." Pollock, in Holmes's "System of Surgery," says: "Perforation of the bowel, that is, rupture of the intestinal coats the result of external violence without any external wound, is by far the most frequently formidable injury with which the surgeon has to contend in practice," and that the spleen and kidneys are "frequently ruptured in injuries of the abdomen." Among the cases reported with this paper it will be seen that, while ruptures of the liver are the most numerous, ruptures of the other organs are not infrequently observed.

RUPTURE OF THE LIVER.

While in the majority of cases of deep lacerations of the liver death follows after a short interval, in some it is postponed for several days; and it is probable that in a few, even after rather deep and severe wounds, recovery takes place. Erichsen says that he has "seen several cases of recovery after injuries probably occasioning lacerations of the liver and followed by peritonitis and jaundice."

Death from ruptured liver is almost invariably due to hemorrhage, usually primary, but at times secondary. Bryant, Pollock and Draper report cases of death from secondary hemorrhage three, five and ten days after the injury, respectively. Erichsen reports a case of death from peritonitis following rupture of the liver.

There are a number of cases on record of death from intercurrent disease, at the autopsy of which it was found that the hemorrhage had ceased, and in some that the liver wound was in process of healing. Case 16 is one of this class.

Ruptures of the liver without involvement of the peritoneal covering are not uncommon (Cases 3 and 8); in these the amount of hemorrhage is comparatively small, and while the destruction of tissue may be great, the prognosis should not be very serious.

Ruptures may occur in the liver in any part of any lobe; they may be single or multiple; they may involve the deep tissues without rupture of the capsule; or they may be simple slits in the capsule.

They may, as in a case reported by Draper, completely divide the liver in two, leaving nothing but a

"finger's breadth of liver substance and peritoneum as a hinge posteriorly"; or, as by Caspar, one where it was "completely ruptured transversely, so that the anterior portion lay loose in the abdominal cavity"; and another, in which "the entire edge of the right lobe seemed as if it had been gnawed by animals."

In the most severe of these cases death occurs within two hours, and the autopsy shows an amount of blood in the abdominal cavity which readily accounts for the rapidly fatal course. Minor injuries to the liver are often found, combined with other conditions of a more serious character (Cases 1, 4, 5, 6, 8, 16 and 17). In Case 3 we have one in which the contused liver tissue has a "point of escape," with resulting hemorrhage into the abdominal cavity.

RUPTURE OF THE KIDNEYS.

While in the opinion of many pathologists rupture of the kidney is of rare occurrence, and Caspar classes it among those "other organs" in which "rupture is almost never observed," the diagnosis of rupture of the kidney is made more often clinically than that of any other organ. This is probably due to the fact that not only is increase in size in or about the organ more easily demonstrated than of the liver or spleen, but that by means of the urinary passages hemorrhage is more apt to show itself. That ruptures of the kidney occur not infrequently is the experience of every surgeon who has much to do with traumatic surgery; and that a rather large proportion of them recover under rest and ordinary care I think would be allowed. Reports of those cases which come to autopsy and operation would lead one to feel that they were even more common than we are apt to suppose. Erichsen says, "The absence of blood in the urine must not be taken as an indication that the kidney is uninjured"; in this connection Cases 20 and 21 are interesting.

There certainly are many cases which appear in the hospital wards after accidents which might well result in severe injuries to the kidneys, which present most of the symptoms of such a rupture, and which in their subsequent history during convalescence simulate very closely cases of rupture, but which are classed as injuries or contusions of the abdomen on account of the absence of hematuria. Ruptures may take place in any part of the kidney, may be one or many, and of all grades of severity; the symptoms which present themselves must vary greatly with their location and importance. Unless there is great laceration of the tissues the peritoneum is not involved; peritonitis rarely follows, but lumbar abscess is not infrequent. Erichsen reports a case in which the ureter was ruptured together with the kidney, and calls attention to this as one of the reasons why hematuria is absent in certain cases.

RUPTURE OF THE SPLEEN.

The spleen is said by most authors to be one of the most frequently injured of the abdominal organs, and from its position and consistency one would expect this to be the case. In the cases which I am able to report it is much rarer than some of the others.

When the spleen is enlarged from any cause it is much more liable to rupture than when of normal size. As in the other organs ruptures may occur in the spleen in any part; they are usually transverse, but not uncommonly are more in the nature of a crush (as in Case 6).

Death after rupture of the spleen occurs at about the same intervals and under the same conditions as after rupture of the liver. One of the most common secondary causes is said to be subdiaphragmatic abscess; and Pollock reports a case of death from subdiaphragmatic abscess and empyema following rupture of the spleen and diaphragm, the result of accident eleven weeks before death.

RUPTURE OF THE PANCREAS.

On account of its deeply seated position it would be natural to suppose that the pancreas would be little liable to injury from external violence. That its position does not entirely protect it is shown in Cases 10 and 11, and that such injuries are not necessarily fatal by Case 22, which was lately at the City Hospital under the care of Dr. H. W. Cushing.

In both Cases 10 and 11 the injury to the pancreas was associated with more severe ones to other organs, and while the amount of hemorrhage from the pancreas is unknown in both cases, it would not appear to be excessive, and it is fair to assume that death was not, in either case, due to the injury to that organ.

In Dr. Cushing's case the amount of hemorrhage must have been slight.

The character of injury to the organ varies in each case. In Case 10 there were "many superficial ruptures and lacerations"; in Case 11 it was "crushed off one inch from its tail"; while in Case 22 the injury, whatever it was, evidently obstructed the outflow of the gland.

Except as it would be modified by the relatively limited blood-supply of the gland, there is no reason why the first effects of pancreatic rupture should differ from similar injuries to other organs.

(To be continued.)

THE FATIGUE OF DEAFNESS.¹

BY CLARENCE J. BLAKE, M.D., BOSTON.

THAT impairment of the hearing power should be an inconvenience is readily understandable; that it may make so large a demand upon the nervous energy as to be a source of fatigue, needs personal experience or observation for its full appreciation.

The investigations of Ogston and others show that the middle ear is usually cleared of its protective cushion of tissue with the first cry, and that the infant is apparently sensitive to sonorous vibrations within a few hours after birth.

The education of the brain through the organ of hearing, therefore, begins at a very early period; and the habitual classification of sounds, in reference to their cause, their indicative importance to the individual, and the location of the sound source, is early assured.

The establishment of a perceptive habit implies provision for the expenditure of nervous energy along a given line, deviation from which necessitates a further expenditure of energy proportionate to the degree of deviation from what was formerly the line of least resistance.

Changes in the tension of the sound-transmitting apparatus of the middle ear and in its sound-transmission incident to disease may so alter or decrease the sounds

¹ Read before the Massachusetts Medical Society, June 8, 1897, and recommended for publication by the Society.

perceived as to make them unfamiliar and needing explanation by a mental process; and the total or even partial abolition of the hearing power of one ear, the other remaining intact, may so far interfere with the ability to appreciate the direction of a sound source, which is one of the habits of normal binaural audition, as to be not only a cause of embarrassment but to make a serious demand upon the nervous energy as well.

To the individual possessed of a reasonably perfect machine, the working limitations incident to possible imperfections in that machine are with difficulty appreciable by any merely mental process, and it is, therefore, only the sufferers themselves or those whose business it is to study imperfections, effect repairs and suggest compensations, that the full cost in expenditure of nervous energy required to overcome an obstacle, either to perception or expression, can be adequately understood.

With the abolition or limitation of one or another of the channels of communication through the human machine, a portion of that nervous energy which is constantly seeking peripheral expression must be expended in the adjustment to the new conditions and the utilization in a compensatory way of other channels of communication.

Given, therefore, a limitation of sight, of hearing, or of tactile sense, an expenditure of energy in what may be termed the conversion of force is required, which evidences itself in the individual as that complex of symptoms to which we give the name of fatigue; and the purpose of this short communication is to direct attention to one form of the mechanism of force conversion, which is evidenced by what may be called the fatigue of deafness.

In view of the fact that the normal ear has very nearly double the amount of hearing power necessary for the ordinary practical uses of every-day life, it is understandable that one-half of the binaural hearing power may be lost without serious inconvenience to the individual; beyond that point of deficiency, however, a distinctly appreciable effort must be made to hear, and, in default of this, a still further effort to gather through other sensory channels such information as may serve to supplement the defective hearing.

The channel which is especially available for this supplementary purpose is that of sight, because through it there may be brought to knowledge the character of the particular mechanical process originating the mode of motion to our appreciation of which we give the name of sound, and the most important illustration of this visual aid to defective hearing is found in the effort to appreciate the sounds of the voice at their true value.

Human speech is made up of a series of vocal sounds, all within a short compass, which are modified, obstructed or terminated by changes of position in the articulating apparatus, to the effects of which we give the name of consonant checks.

A superficial study of these checks shows that some of them are formed in the front, some in the middle and some in the back of the mouth; that they are, with few and slight exceptions, accompanied by a greater or less degree of resonance in the nasal and pharyngeal cavity, and that they vary considerably in the amount of muscular energy required for their production; and furthermore, that the principal distinction to the ear between such consonant sounds as are similar in character is due to the greater or less preponderance of a small number of qualitative overtones.

Further than this we are aware that the consonant sounds which nearly resemble each other, in both force and musical value, are produced by the coördinating operation of very nearly the same sets of muscles, and therefore are accompanied by very nearly the same facial expressions.

Given, therefore, an average case of marked impairment of hearing, the result of a slowly progressive middle-ear disease, the patient will hear most readily the consonant sounds which require most force in their production; these include four explosives—*t, d, p* and *b*—which very nearly resemble each other in force and tone value; they are, however, formed in the front of the mouth, *p* and *b* being distinctly labial, and *t* and *d* as distinctly formed by the contact of the tip of the tongue with the upper incisors. From the position and formation of these consonants and the necessity for distinguishing between them, it usually ensues that their differentiation makes the first step in that instinctive study of lip reading, which to the appreciably deaf person becomes eventually more or less habitual, and which offers another channel for the expenditure of nervous energy in the effort to see, as well as to hear, the spoken word.

The other consonant sounds having the greatest logographic or force value, *k* and *g*, for instance, are those formed in the back of the mouth, and are accompanied by a lesser degree of recognizable facial expression than the front consonants, while the consonants having the least force value—*f, l, n, m*, for instance—very nearly resemble in the mechanism of their construction the harder consonant sounds of nearly the same musical value.

It thus comes about that the deaf person will, when a soft consonant occurs in a sentence, substitute for it, mentally, the hard consonant sound most nearly resembling it, which would have been heard had it been used. In any given sentence, therefore, there are to the very deaf, though seeing persons, certain consonant sounds which are distinctly heard, others which are imperfectly heard, others which are detected by sight, and still others which are merely inferred.

In high grades of imperfection of hearing, therefore, both the effort to hear and the effort to see combined are inadequate to the presentation to the mind of the complete spoken sentence, since there remain gaps in the array of consonant sounds which must be filled in judiciously from the context, and the completion of the sentence thus presented means the solution of a puzzle and a third demand upon the nervous energy in addition to that required to hear and to see.

In other words, the exercise of the ordinary communication with his fellow men demands of the deaf person the operation of three distinct brain processes to achieve that which is normally accomplished without conscious effort, and the resultant fatigue may be justly estimated as a possibly important factor in many cases of nervous overstrain.

SURGEONS IN ORDINARY TO THE PRINCE OF WALES.—Sir William MacCormac, president of the Royal College of Surgeons, and Alfred Dowling Fripp, assistant surgeon to Guy's Hospital, have been appointed surgeons in ordinary to His Royal Highness. Mr. Fripp obtained his licentiate in the Royal College of Surgeons only eight years ago and was but recently appointed assistant surgeon to Guy's Hospital.

SOME OF THE INDICATIONS FOR OPENING THE MEMBRANA TYMPANI¹

BY FREDERICK L. JACK, M. D., BOSTON.

THE operation of opening the drum membrane for the evacuation of fluid is often neglected. The demand for this procedure becomes imperative, not only in most cases of acute middle-ear inflammation, but also for the relief of fluid collected in the middle ear without acutely inflammatory movement. It is to the practicability and technique of the operation in these conditions that I would call attention.

Indications for Operation.—There are probably very few practitioners at the present time who do not recognize the importance of an early paracentesis in cases of acute middle-ear inflammation accompanied with severe pain, marked injection and bulging of the drum membrane. By the operation several desirable ends are at once attained. In the first place, the loss of blood, together with evacuation of collected fluid, relieves the pressure and thereby lessens, if not stops, the pain. The rapid healing of cut surfaces, as compared to that of the ragged tear generally produced by spontaneous rupture, has a decided bearing upon the subsequent improvement in hearing. I believe also that an early incision prevents the chances of mastoid complication. The ear trouble in very young children is frequently overlooked, a chance observation of aural discharge first attracting the attention. Children usually offer little in the way of objective symptoms; they seldom place the hand over the affected ear, or in any way direct attention to the seat of trouble, whereas the general reflex nervous disorders, caused by the auditory disturbance, cover a wide range of symptoms, from slight twitching to a condition practically of opisthotonos, and to marked retraction of the legs, like that seen in acute abdominal affections.

The fact that more pronounced nervous symptoms result from middle-ear inflammation in young children than in adults is chiefly due to anatomical conditions. In the attic, or upper wall of the tympanic cavity, is found a suture (*sutura petrosa-squamosa*), the connective-tissue covering of which has an intimate relation with the dura mater. This suture in adults is closed by bone, often very thin bone, which retards or prevents the extension of the middle-ear trouble to the dura mater or brain. An examination of the ears in infants and young children will often make clear the diagnosis, and rapid disappearance of alarming nervous symptoms will follow an early free opening of the bulging and inflamed *membrana tympani*.

There is another condition in which an opening in the drum membrane is of great service, and one the importance of which is less frequently recognized than that we have just briefly considered. I refer to the collection of fluid, either serous or mucous, in the tympanic cavity, following an acute catarrhal inflammation of the nose and throat. The symptoms naturally arising include impairment of hearing, a feeling of pressure or fullness, autophonia, tinnitus aurium, and possibly vertigo. The onset is often very sudden, and frequently follows too vigorous attempt at clearing the nose by blowing. The drum membrane upon inspection is found depressed from closure of the Eustachian tube, but there is seldom any considerable injection of blood-vessels. The color of the drum varies with the

relative thickness of the membrane and the nature of the fluid, serous exudation producing a straw color, mucous a dark gray. Often the level of the fluid is indicated by a dark line. In many cases, however, due to pathological changes in the *membrana tympani* previous to the attack, it is impossible to see the fluid. We then rely somewhat on the history and upon hearing râles by means of the antroscope after inflation of the middle ear.

I am fully aware that many of these cases improve under other treatment, but I am equally certain that many cases of progressive catarrhal deafness are made permanently worse by neglecting to free the middle ear of its fluid contents. I make this statement advisedly, and with considerable experience in the treatment of these cases, both in the usual way, and by incision through the drum membrane. I have yet to meet a case in which complete evacuation of the fluid through an opening in the drum proved other than most satisfactory. On the contrary, it is not an uncommon experience for cases with undoubted history of fluid in the middle ear to present themselves for treatment after the usual means have been employed, with membranes collapsed and held more or less firmly in place by adhesive bands. The operation is not difficult, provided the field is properly illuminated; it is only slightly uncomfortable, and the opening usually heals in twenty-four hours.

Technique of Operation.—The auditory canal and drum are first rendered aseptic by instillations of a one-to-five-thousand corrosive-sublimate solution; after drying with absorbent cotton a few drops of a four-percent. cocaine solution are applied to the drum by means of the cotton holder. The point of election is in the posterior lower quadrant. A very small incision is quickly made by a quick thrust of a sharp triangular knife, the fluid being forced out by inflation. The ease and rapidity of evacuation depend upon the nature of the fluid, thick mucus often requiring the use of small forceps, after presenting at the opening; serous fluid, on the other hand, escapes into the auditory canal, and is removed by means of absorbent cotton. Several inflations of the middle ear, by means of the catheter or Politzer bag, are usually necessary to completely evacuate the middle ear. A small plug of cotton is placed in the meatus for twenty-four hours, then removed, and subsequent treatment is directed to the naso-pharynx and Eustachian tube. The relief afforded by paracentesis is immediate, and with appropriate treatment, the danger of refilling slight.

Early paracentesis, under the two conditions I have indicated, will often avert alarming symptoms, and prevent serious results, not only as regards the hearing but even the life of the patient.

The suggestions offered in this brief communication are based not simply upon theoretical considerations but upon practical experience, and I am convinced that the importance of the subject has not been and cannot be overestimated.

BICYCLE ACCIDENTS.—In last July, during about half of which it was raining and consequently few wheels were out, the New York newspapers reported forty-eight more or less serious accidents from bicycling. Most of the sufferers were those riding the wheel, but there were also many children run down while playing in the street. — *Medical Record*.

Clinical Department.

A CASE OF GASTRIC ULCER IN A CHILD FOUR MONTHS OLD.¹

BY CLEON M. HIRBARD, A.M., M.D.;

First Assistant Resident Physician, South Department, Boston City Hospital.

GASTRIC ulcer in children is such a rarity that only a few cases have been reported.

A. H. Hare² collected in literature 14 cases under fourteen years, with but five under three years of age.

Colgan³ has added another case in a girl two and a half years old, who was ill thirteen hours with convulsions and high temperature. Autopsy showed a round ulcer on the greater curvature near the cardiac end of the stomach, which had perforated, causing a peritonitis.

Rotch⁴ reports a case of Dr. Northrup's in a female one year old. "The infant was under treatment for one month. It had vomiting and diarrhea. In the second week it began to refuse its food and to emaciate. The diarrhea continued and the vomiting was persistent. The vomitus was somewhat brownish in color; the child died of exhaustion. The mucous membrane of the stomach was covered with small ulcers, varying in size from a dot to one centimetre in diameter." There was one large ulcer which had perforated the wall. There was some necrosis around the ulceration, but "no evidence of inflammatory condition."

There was no note of tuberculosis in either Colgan's or Northrup's case.

Holt in his recent book, "The Diseases of Infancy and Childhood" (p. 304), divides gastric ulcer in children into four classes: (1) ulcer in the new-born, (2) ulcer resulting from follicular gastritis, (3) tubercular ulcers, (4) round perforating ulcers. Of the latter class he says that he has found but three cases on record in non-tubercular patients. Two were in young children.

As to the pathology of these ulcers little is known. Holt (p. 101), in speaking of ulcers in the new-born, says: "The cause of these ulcers is somewhat obscure; some of them are undoubtedly dependent upon inflammatory changes, probably of infectious origin; others have been compared to peptic ulcers of later life, and are attributed to thrombi in the blood-vessels of the mucous membrane."

Annie D., age three months, was admitted to the Diphtheria Ward, South Department of the Boston City Hospital, March 20, 1897, having been ill for two days with fever and vomiting. There was no membrane, but the Klebs-Löffler bacilli were found in the throat. She was of good color and well developed and nourished.

On admission she received an immunizing dose of antitoxin, which was followed four days later by a morbilliform eruption which persisted three days. On the 26th the temperature rose to 102.5°, having been practically normal before that. She also began to vomit up the milk and lime-water. On the 30th the milk was not retained, and a small amount of Mellin's Food was given, which was retained in part. From the 22d there had been some diarrhea, which had increased by the 30th, the stools then being green in

color with some curds. On the 31st they were brownish in color. From this time to the end the diarrhea and vomiting persisted. She was irritable and restless, cried most of the time, and lost flesh rapidly. The temperature varied from 99° to 101°, pulse from 120 to 150, respiration from 20 to 35. April 3d there was slight retraction of the neck backwards, pupils pin-point in size but reacted to light. Pulse very weak and thready, no food was retained, diarrhea continued, marked stupor and pallor. Died next morning of what appeared to be exhaustion.

The following description of the autopsy and microscopic examination are from the records of the Pathological Department of the Boston City Hospital, April 4, 1897:

AUTOPSY.

Body of a child about six months of age; well developed, rather poorly nourished. Rigor mortis. Body very pale; no lividity. The abdomen greatly distended, tympanitic everywhere; muscles pale. Intestines distended with gas, contents discoloring intestinal wall brownish-black. Tonsils, naso-pharynx, larynx and trachea normal. Heart, weight 40 grammes. Muscle pale; valves and cavities normal. Lungs normal in color, generally soft, except in backs, where a few small solid nodules can be felt. Bronchi covered with slimy mucus, membrane injected. On section, lung normal, except at base where small consolidations finely granular, dark-red in color, are present. Liver, weight 570 grammes. Pale brownish-red, mottled slightly; markings normal. Spleen, weight 40 grammes. Attached by firm adhesions to lateral abdominal wall; of a light-red color; malpighian bodies showing as white pin-point areas. Pulp normal. Kidneys, 115 grammes. Pale, soft; markings normal; capsule peels smoothly.

Stomach contained white masses resembling curdled milk, covered with black granular *debris*, semi-fluid, in large amount, distending stomach somewhat. On the posterior surface, extending down to greater curvature, and nearer pyloric than cardiac orifice, a circular area, five centimetres in diameter, partially outlined on either side by deep losses of substance. On one side 2.5 by .6 cm., rather elliptical; on the other 3 by .5 cm., with its greatest breadth in the middle portion of ulceration. In these places the circular layer of muscle fibres is laid bare, the edges are prominent, firm and undermined. In the area included between these ulcerations the mucous membrane is soft, rather prominent, and presents many small punctate losses of substance, usually circular, about the size of a pin's head and superficial, being apparently confined to the mucous membrane. Tests of the black *debris* for hemin crystals were positive.

Intestines contained considerable quantities of blood-colored material in upper portion, with black granular material in large amount further down. The mesenteric glands enlarged from size of pea to that of a bean; white, hard. On section, rather firm.

Aorta normal. Bladder and genitalia normal.

Anatomical diagnosis: Bronchitis and broncho-pneumonia, gastric ulcer with hemorrhage.

Bacteriological examination: Liver, colon bacilli; spleen, colon bacilli and few streptococci; kidney, streptococci (pure).

MICROSCOPIC EXAMINATION.

Sections of the kidney show granular, coagulated material in tubes, with a few pale circles. Some swelling of epithelium of convoluted tubules. The epithelium over glomeruli well marked. In a few places in the cortex there is cellular infiltration in the interstitial tissue, more or less focal. The infiltration is chiefly made up of plasma cells. The tubules are compressed in these places and almost obliterated. Closer examination of the kidney shows not one but several foci of typical interstitial nephritis in the cortex.

Section of the liver shows some cellular proliferation

¹ Read before the Boston City Hospital Medical Society, May 13, 1897.

² Keating's Cyclopaedia of the Diseases of Children, vol. iii, p. 51.

³ Medical News, Philadelphia, vol. lxi, p. 408.

⁴ Pediatrics, p. 253.

around the portal spaces, and numerous leucocytes in the capillaries. Swelling and fatty degeneration of liver cells.

The spleen is intensely hyperemic; the follicles enlarged. In one of the large follicles there is a pale centre, many of the large cells in which are necrotic, the whole resembling a tubercle. In the necrotic tissue there are polymuclear leucocytes.

Examination of the stomach shows a sharply circumscribed loss of substance, with deeply undermined necrotic edges on one side; and at the other the loss of substance gradually fades out to the surface of the mucous membrane. In the submucosa there is considerable cellular infiltration and accumulation of cells in the vessels. The base of the ulcer is necrotic, and in places it extends down through the sub-mucosa to the muscular coat; there is a small amount of fibrin in the tissue beneath. There is no granular tissue and no chronic inflammatory reaction. Where the ulcer is most undermined, fibrin is seen in the sub-mucous tissue, due to fibrinoid metamorphosis of the connective tissue. At various places beneath the mucous membrane and adjoining the ulcer there are distinct hyaline thrombi in the walls of the blood-vessels, and hyaline masses completely occluding them.

It is possible that the ulcer is not to be regarded as a typical chronic gastric ulcer, but as a more acute process due to a disturbance in the circulation in the stomach produced by the hyaline thrombi, and the necrotic mucous membrane has been afterwards completely digested away by the action of the gastric juice. It is also possible that the ulcer started as a distinct diphtheritic lesion of the mucous membrane. The fibrinoid metamorphosis of the connective tissue and the hyaline thrombi in the vessels are not opposed to this view, for similar changes are not uncommon at the base of the diphtheritic ulcers in the pharynx.

In the few cases of diphtheritic lesions of the stomach which have come to observation the process was more diffuse and would not have led to circumscribed ulceration.

GASTRIC ULCER IN THE NEW-BORN.

ETIOLOGY, MATERNAL IMPRESSIONS.

BY J. R. LINCOLN, M.D., MILLBURY, MASS.

On November 4, 1896, Mrs. —, of Lowell, while visiting Mrs. C., her sister, of this town, was taken suddenly ill, and vomited a large quantity of bright-red blood, which spattered over her clothing and made quite a pool on the floor. She was found in a faint by Mrs. C., who got her into the house, washed off the blood, changed her clothing, and took the whole care of her for two days, until a particular nurse who was desired could arrive. During these two days the patient vomited blood several times. Blood was also noted in the stools.

Mrs. C. understood perfectly the nature of the case; but beyond being anxious for her sister and shocked by the spectacle of blood, did not show any nervousness, asked about the case and wondered if it would make her have a miscarriage.

For four weeks the patient remained at her house, at the end of which time she was able to return to Lowell, where she was referred to her physician, Dr. W. T. Carolin, for convalescence.

At the time of this illness, November 4th, Mrs. C. was almost exactly five months pregnant, and, as we have seen, did not appear to be unduly alarmed or nervous over her sister's hemorrhage or following illness.

On March 3, 1897, at 6 o'clock P. M., a girl was born naturally, weighing eight and one-half pounds, and to all appearances absolutely perfect. On the next day the baby was very uneasy, cried all the time, and at 4

o'clock P. M. vomited one or two teaspoonfuls of bright-red blood. This was followed by several vomiting spells on the succeeding day; this time the blood was darker colored.

For three or four weeks the baby cried about all the time, seldom sleeping an hour continuously. The mother did not wish to nurse the child, and I was able only after much experiment to obtain a satisfactory food and method of feeding. Notwithstanding all this, it finally did well. At two weeks it weighed but six pounds; at four months thirteen pounds, with no digestive disturbance after the second month.

In face of such facts as the above, are we justified in excluding as "happenings" all cases of maternal impressions?

Medical Progress.

RECENT PROGRESS IN SURGERY.

BY H. L. BURRELL, M.D., AND H. W. CUSHING, M.D.

(Continued from No. 7, p. 156.)

RADICAL CURE OF HERNIA WITHOUT THE USE OF BURIED SUTURES.

Duplay and Cazin,¹² having seen late abscess-formation as the result of the use of buried sutures, believe that they form a *locus minoris resistentiæ*, and that however aseptic they may be, a systematic septic infection is liable to show itself at that point. They therefore advise the performance of an operation without the use of buried sutures, and accomplish this by tying the sac upon itself, after having drawn it well down; and to prevent this knot from slipping, they tie a series of knots in the sac, or divide it and tie the two portions together, one knot upon another.

The parietal sutures and those employed to occlude the external ring are of silver wire, and are removed after union has taken place.

A series of twenty operations performed in this manner have yielded results as perfect as could be desired, with no recurrences and no abscess-formation.

SURGERY OF THE NON-CARCINOMATOUS DISEASES OF THE STOMACH.

Doyen¹³ has come to the conclusion that the painful symptoms in dyspepsia, hyperacidity and ulcer rotundum are due to reflex spasm of the pylorus. He assumes that the cicatrization of gastric ulcers is hindered mostly because of the spastic contraction of the pylorus, which keeps the edges of the ulcer constantly irritated.

For this reason, Doyen performed the operation of gastro-enterostomy in a case of gastric ulcer, with the result that the pain and vomiting at once ceased; and at the end of three years the patient still remains well. Doyen has entirely abandoned pyloroplasty. He has performed gastro-enterostomy 48 times with a total mortality of 30 per cent.; 16 cases were for carcinoma, 11 for cicatricial stenosis of the pylorus and duodenum, and 21 for spasm of the pylorus due to gastric ulcer and hyperacidity. All of these latter cases recovered completely. In one case the function of the stomach was not well performed after the operation, though the pain was entirely cured and the patient gained in weight.

¹² La Semaine Médicale, November 11, 1896; American Journal of Medical Science, March, 1897, p. 354.

¹³ Annals of Surgery, February, 1897, p. 212.

For the removal of neoplasms, the author prefers the operation of Billroth. Out of eleven operations there were four deaths. Two of these were operated upon when *in extremis*. A third had empyema of the gall-bladder with consecutive stenosis of the duodenum, and perished from sepsis.

In closing, Doyen reported an operation for hour-glass contraction of the stomach with torsion of the two halves upon one another, consisting in gastro-enterostomy in the upper segment.¹⁴

THE OPERATIVE TREATMENT OF DILATATION OF THE STOMACH.

Ewart and Bennett¹⁵ report an operation for dilatation of the stomach, which they believe to be new.

The abdomen having been opened by a median incision about five inches long, commencing above at a point an inch below the ensiform appendix, the stomach was thoroughly examined by the hand introduced through the wound. No adhesions were detected, and the pylorus was normal. The viscus was then drawn out of the abdomen and laid upon the parietes, where it presented a large balloon-like bag distended with gas. A fold on the anterior aspect of the stomach was then turned in by the fingers of the assistant. The length of this fold, which followed the direction of the long axis of the stomach, was about twelve inches, its greatest depth being about three inches. While this fold was held involution by the assistant's fingers the peritoneal surfaces on the opposite sides of its base were brought together by numerous sutures made to transfix the peritoneal and muscular coats, the fingers of the assistant being gradually withdrawn from the fold before the tightening up of the final stitches. After the stitches had all been fastened off, the size of the stomach was greatly lessened. Mr. Bennett had intended to make a small secondary involution at the great end of the stomach to prevent the otherwise inevitable dependent tendency of that part; but as the patient was in a very unsatisfactory condition generally, it was thought wiser to be content with what had already been done. The altered viscus was then returned into the abdomen, the wound in the parietes being closed by fishgut sutures in the usual way.

The patient presented the ordinary symptoms of dilatation of the stomach in a marked degree. He had had the benefit of the various forms of palliative treatment without any relief. The patient, after leaving the hospital, was able to resume his work, which was that of a carpenter.

Under the title of "Gastropexy," Duret describes¹⁶ an operation for the condition of dilatation and downward displacement of the stomach, which is known as gastropexia of Glenard's disease. The operation is performed as follows: An incision four inches in length is made in the middle line of the abdomen, beginning at the ensiform cartilage. The peritoneum is divided only in the lower half of the wound, the upper portion being left undivided to receive the sutures which hold the stomach in place. The pylorus and lesser curvature are then fixed to the anterior abdominal wall as follows: The stomach having been raised and placed in its normal position, a silk suture is made to include the serous and muscular coats of the pyloric

extremity, and is then passed through the overlying portion of exposed peritoneum from within outward. The suture is carried backward and forward in this way until the stomach has been well anchored. The external wound is closed layer by layer.

A NEW OPERATION FOR GASTROSTOMY.

Fontan¹⁷ gave the following as the steps in a new operation which he has employed successfully, and which has for its object the avoidance of erosion, the infiltration of surrounding tissues, etc., due to the escape of the gastric juice. This method simplifies other methods for the formation of valvular openings, and the author terms it the valvular procedure. First, the ordinary epigastric incision; second, the seizure of the stomach with a pair of toothed forceps and the production of a hernia of considerable size; third, the suturing of this fold to the edge of the wound; fourth, the invagination of the fold, the forceps still remaining in the position, and the suturing together of the serous surfaces at the ends of the wound; fifth, the incision of the stomach wall by a bistoury passed along the forceps, and the insertion of the canula.

The canula is thus placed in a valvular opening formed like an inverted bishop's mitre, with the walls of the stomach forming its gastric surface, while the serous surfaces are opposed to each other. The results obtained are perfect, no contents or gastric juice escaping through the valve thus formed.

GASTRECTOMY.

Peau¹⁸ reported to the French Surgical Congress the results he has obtained in operations of this character. In 12 pylorotomies for cancer he had four deaths; in three gastro-enterostomies, one death. Outside of cancerous disease all his other operations were successful — four pyloroplasties and four excisions of ulcers.

Within the last twenty-five years the following operations have been employed against this disease: pylorotomy, gastro-duodenostomy (the radical operations), and gastro-enterostomy, a palliative operation.

Pylorotomy is indicated in young persons who are still resistant, where the tumor is small, mobile and has not produced lymphatic and visceral metastasis.

In every case where the first portion of the duodenum alone is involved, and it is possible to resect the diseased portion of the stomach and yet retain a small portion of the cardiac end, the surgeon may interfere; but instead of attempting to unite the duodenum to the large opening in the stomach, this should be sutured in different planes, and the duodenum united to the nearest portion of the stomach, preferably by a Murphy button.

In case of marked cachexia or lymphatic involvement, one should be contented with a gastro-enterorrhaphy with a Murphy button.

GASTRO-ENTERO-ANASTOMOSIS: ENTERO-ANASTOMOSIS: CHOLECYSTENTERO-ANASTOMOSIS WITHOUT PRELIMINARY OPENING OF THE ORGANS TO BE ANASTOMOSED.

Souligoux¹⁹ describes the following operations:

¹⁴ Verhandlungen der deutschen Gesellschaft f. Chir.; XXIV Kongress, 1895.

¹⁵ Lancet, London, 1896, vol. ii, No. 1; American Journal of Medical Sciences, September, 1896, p. 343.

¹⁶ Revue de Chirurgie, June 10, 1896.

¹⁷ Revue de Chirurgie, November 10, 1895; American Journal of Medical Sciences, March, 1897, p. 353.

¹⁸ Loc. cit.

¹⁹ La Presse Medicale, 1896, No. 59; American Journal of Medical Sciences, February, 1897, p. 221.

He produces on each of the two organs to be anastomosed an area of sphacelus. These two points are brought together, face to face, and retained by sutures; peritoneal adhesions form. At the end of forty-eight hours the sphacelated zones fall in, and the adhesions are more than sufficient to prevent separation of the two organs. The instruments needed are a pair of powerful forceps, a small Reverdin needle, No. 3 silk, and solid caustic potash.

Gastro-Entero-Anastomosis. — After celiotomy the first loop of jejunum is sought, and a silk thread is passed through the mesentery, in order to draw the intestine out of the abdominal cavity. The intestine at the proper point is caught between the blades of the forceps and compressed with all the force the operator can employ. The two intestinal walls are thus made so thin that they are transparent. The same manoeuvres are repeated upon the stomach. Here it is important that the assistant exposes well the fold formed on the stomach, and that he does not allow the mucosa to slip until it is secured in the grasp of the forceps.

Two fortified zones are thus determined on the two organs, the surfaces of which soon take on a black coloration. The peritoneum only has resisted the crushing effect of the forceps. The line of suture is commenced about two millimetres from the margin of the contused area, uniting the two inner surfaces throughout their entire extent. At this moment the crushed surfaces are cauterized with caustic potash, after which the assistant sponges the area thus cauterized. The sutures are then placed in the two external borders. If any discolored area appears outside the suture, this point is inverted by additional sutures. The operation may be completed in twenty minutes. It remains only to close the abdominal cavity.

Entero-Anastomosis is performed in the same manner as the gastro-enterostomy.

Cholecystentero-Anastomosis. — The author has endeavored to produce something analogous to the ampulla of Vater. In this procedure he opens neither the gall-bladder nor the intestine. Upon the intestine he traces an elliptical incision, two centimetres wide and three centimetres long, comprising only the serous and muscular coats. The flap thus made is removed. The mucosa exposed is compressed and cauterized to the extent of half a centimetre. Upon the anterior and posterior face of the gall-bladder a small needle, carrying a fine silk thread, is passed. The posterior thread is attached to the posterior border of the intestinal wound, the summit or base of the gall-bladder is crushed and cauterized with the potash, and the anterior thread is passed through the intestine in front of the intestinal wound, the posterior thread having already been so placed. On drawing on these threads the gall-bladder is invaginated in the intestinal canal, and while retained in this position by the assistant making traction on these threads, the suture around the margin of the anastomosis is made. The two original threads are then removed. At the end of four hours the sphacelus falls in and the communication is complete.

FORMATION OF GASTRIC FISTULE.

F. Fischer,²⁰ Strasburg, reports a method by which

he has successfully established a gastric fistula in a case where contraction and infiltration of the gastric wall made it so rigid that it could not be brought out through the abdominal wound. In such cases the method of Witzel or Frank for performing gastrostomy to relieve esophageal strictures is impracticable. Fischer operates as follows: The abdomen is opened and the stomach fixed to the wound edges till adhesive inflammation has shut off the peritoneal cavity. During this time the patient is fed by nutrient enemata. After usually three days liquid food is introduced into the stomach through a hypodermic needle which is passed diagonally through the stomach wall at the middle point of the area exposed in the abdominal wound. By carefully rotating the needle it penetrates the wall. It can be easily known when it has entered the stomach. Three ounces of fluid (50–60 grammes) are injected, and the needle withdrawn. After three to five hours the process is repeated at the same point. After five or six days a larger needle can be passed and thicker fluids injected. By always passing the needle in the same line a diagonal canal is finally formed. In one case a hard rubber catheter was introduced after eight weeks. The walls of the sinus collapsed when this was withdrawn so that no fluid escaped. Fischer has operated on four patients with esophageal stenosis — three being the result of cicatrices, one due to cancer.

A NEW METHOD OF ENTERO-ANASTOMOSIS.

Souligoux²¹ has devised a new method of intestinal anastomosis, which consists in suturing two loops of gut without opening them. With a strong clamp he pinches, in a longitudinal direction, the free border of the two intestinal loops, and then stitches them together along one margin of the compressed areas. These areas are then touched with caustic potash, and the suture completed around them. The cauterized portions of the gut necrose, and fall into the lumen of the intestine, and communication is established. In animals, this takes about forty-eight hours. This operation has been performed upon man several times with success.

Chaput has performed a similar operation, using a Paquelin cautery in place of caustic potash. If the stomach enters into the anastomosis, he first removes the muscular coat of the portion involved. Retention of feces is a contraindication. The chief advantage of the operation is the rapidity with which it may be performed.

THE TREATMENT OF INTESTINAL INTUSSUSCEPTION.

This subject has been revised and rewritten to date by Rydygier.²² A very satisfactory summary of this interesting article has been published by Dr. J. P. Warbass.²³ Rydygier claims that the poor results after operation are due to the fact that the operation has been done late. The mortality will be less when intra-abdominal intestinal strangulation is recognized and treated similarly to strangulated intestinal herniæ. The point which is of importance in deciding the time for operative treatment is the acute or chronic character of the intussusception. The kind of operation also depends on the same fact.

In acute cases operation should be done at once

²¹ Gazette heb. de Med. et Chir., July 23, 1896; Medical News, September 12, 1896, p. 294.

²² Verhandlungen der deutschen Gesellschaft f. Chir., XXIV Kongress, 1895.

²³ Annals of Surgery, 1896, vol. xxiv, p. 243.

²⁰ Verhandlungen der deutschen Gesellschaft f. Chir., XXIV Kongress, 1895.

after a reasonable trial of the usual non-operative procedures; for example, gastric lavage, rectal injections of gas or water in the knee-chest position, massage, or gentle manipulation with full narcosis. A cure by spontaneous disinvagination or sloughing of the invaginated segment is no more to be expected than in a strangulated hernia. Rydygier operates after two unsuccessful attempts at reduction by rectal injections of water, in acute cases, as soon as possible.

After laparotomy has been done, disinvagination is to be attempted if it can be done without especial difficulty. If the vitality of the intestinal wall is doubtful, especially at the point of constriction, the affected point is packed off by iodoform gauze from the general peritoneum and the abdomen left unclosed. Of 24 cases where reduction was possible and the intestine disinvaginated, eight recovered.

When disinvagination cannot be done, the intussusception should be resected; and the operation is described. The entire mass is to be resected, however, when the invaginating sheath shows changes indicating impaired vitality and perforation.

The formation of an artificial anus should only be done in cases of collapse when there is not time for any other method. Intestinal anastomosis is also undesirable, for it leaves the disease untouched. It restores fecal circulation, but statistics fail to show that it results in recovery.

In chronic cases there is more opportunity for a trial of non-operative procedures, and such means should always be tried; but temporizing without some especial reason is not desirable.

As in acute cases, disinvagination is the first operative procedure which should be tried. This has succeeded, with recovery, after invagination of six and nine months.

When impossible, resection of the intussusceptum is more strongly recommended than in acute cases. Intestinal anastomosis is indicated only in cases with extensive adhesions. The mortality is less than in acute cases. There is no reason for the formation of an artificial anus in chronic cases.

Operations should be done at a time when acute symptoms are absent.

THE TECHNIQUE AND INDICATIONS FOR RESECTION OF THE RECTUM IN CASE OF CANCER.

Depage²⁴ gives the following as the technique he employs in cases of cancer of the rectum:

(1) The patient is placed in the gynecological position, in such a manner as to give to the pelvis a vertical direction. An incision is made on the posterior aspect of the pelvis, and the coccyx and one or two sacral vertebrae are resected if it is necessary.

(2) The dissection of the rectum, care being taken to leave as much of the cellular tissue and peritoneum adherent to it as possible, finally preserving the superior hemorrhoidal artery in order to maintain the nutrition of the superior portion and to remove the cancerous tissues *en masse* with the lymphatics involved by the disease.

(3) Closure of the peritoneal cavity immediately after the resection of the intestine and the removal of the neoplasm.

(4) Drawing down of the superior segment of the anus after having invaginated it into the inferior seg-

ment, even for cancers situated high up. There is no danger of gangrene of the intestines if care is taken to preserve the superior hemorrhoidal artery.

In one case, however, gangrene occurred, but this case supported the view already expressed, for after the removal of the necrosed tissue he found the superior segment and united it to the anus, without in this instance leading to gangrene and necrosis.

The fifth step is tamponing or suture in layers.

The author does not use the palliative iliac artificial anus except under two conditions:

(1) Where operation is urgent and the general condition of the patient is bad.

(2) If the cancer is so extensive that the sacrifice of the entire rectum is necessary.

The author obtained in ten cases eight recoveries. One case was seen three years and a half after operation, one a year and a half after, while two died from a return of the disease one year after the operation. The others have been operated upon too lately to be of value statistically. Relapses are more rare and later in disease of the rectum than in cancer of any other portion of the body.

As indications, the author says that at the beginning of the disease the radical operation is imperative; later, when the lymphatics are involved, the radical operation or an artificial anus, according to the extent of the involvement and the condition of the patient; later, when extirpation is impossible, the artificial anus is the only and temporary relief.

(To be continued.)

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

JAMES G. MUMFORD, M.D., SECRETARY.

REGULAR Meeting, Monday, March 22, 1897, Dr. A. L. MASON in the chair.

ORAL COMMUNICATION.

DR. A. H. NICHOLS: I have two patients to show to the Society, illustrating cases of accidents and interesting from their rarity. The first is a tumor, a hematomia, of the inferior mediastinum. A laboring man, while crossing the street, was knocked down by an electric car and probably pressed between the fender and the pavement. There appeared at once a globular swelling projecting from the mediastinum between the seventh rib and the ensiform appendix of the breastbone. This occurred three weeks ago to-day. The tumor reached its height about a week after the injury, and has since been subsiding. As seen to-night it does not extend over the space between the sixth and seventh ribs as it did a week ago, but still forms a very decided tumor and becomes more prominent when the patient coughs. The tumor occupies the position of the internal mammary artery at the point of its bifurcation between the sixth and seventh ribs; but it cannot be determined whether the hemorrhage arose from that artery or from the anterior intercostal.

The second patient presents a more complicated lesion of the chest-wall. This man was riding on a bicycle when he came into collision with a vehicle, the

²⁴ Rev. de Chir., November 10, 1896; American Journal of Medical Sciences, March, 1897, p. 352.

shaft of which appears to have broken in the chest-wall. At the point marked in ink there is an ununited fracture of the fourth rib. By pressing on the rib the free end of the inside fragment can be distinctly felt. Inside of the mammary line on the fifth rib is another ununited fracture. There is a deformity also of the second rib indicating probable fracture at the junction of the cartilage and the rib. The hospital record gives a history of pulmonary emphysema. He had a cough with bloody expectoration, very high rate of respiration for about three weeks and there remains a chronic vesicular emphysema. As he coughs it will be observed that the lung fills up the intercostal spaces and projects a little beyond. I have called this lesion vesicular emphysema, this being the term first proposed by Laennec, which is in reality a misnomer. Strictly speaking, emphysema is limited to the infiltration of air into the interlobular areolar tissue or into the subpleural areolar tissue. The theory originally pronounced by Rokitsansky seems to fully explain the situation in this case: that there is produced a histological change in the lung resulting from perforation by the broken ribs; that the septa of the vesicles become subsequently atrophied and perforated until several cells coalesce. In looking up the literature of *emphysema vesiculare* I found one case reported by Guttman of Berlin in which the lung was nearly converted into one large vesicle.

This occurred September 19, 1896. The question is how much was he disabled by this injury and what will be the ultimate result of the emphysema. He does not make any complaint of breathing, but the pressure of the outer fragments into the lung gives difficulty on working, therefore he is incapacitated for heavy work. The emphysema, by reason of its tendency to impair the nutrition of the lung, must be regarded as a progressive disease. There is no cardiac complication.

DR. C. P. PUTNAM: This tumor makes its appearance outside of the ribs. It would seem that it must be a subcutaneous cavity connecting with the lung, rather than a cavity in the lung itself. An emphysematous cavity in the lung itself could, one would think, at best only cause a bulging between the ribs.

DR. NICHOLS: If that had been the original lesion, I think the air would have long since been absorbed. If there were infiltration of air from the lung into the subcutaneous cellular tissue there would be present the unequivocal physical signs of pneumothorax. In the few cases recorded of traumatic emphysema the inflation and projection of the lung correspond identically with what we find in this man. As here the pectoral muscles usually undergo atrophy.

DR. EDWIN W. DWIGHT read a paper on

RUPTURES OF THE VISCERA AND THEIR CONNECTION WITH SURGICAL SHOCK.¹

DR. WHITNEY: In experiments on animals injury of the suprarenal capsule is at times associated with rapid death of the animal without other changes in the body. The capsules are very small bodies and easily overlooked. Attention should be directed to the suprarenal capsules in cases where lesions of other organs are insignificant, as a rupture of them might be a death factor. The intimate connection of these with the large ganglionic centres of the abdomen has been noted.

¹ See page 171 of the Journal.

THE PRESIDENT: The reader spoke of pneumonia as following chest injuries; I should like to inquire whether after chest injuries true lobar pneumonia is a common sequence, and if so after what interval, early or remote.

DR. DWIGHT: In 511 cases of fractured rib there were 40 deaths; 29 died in three days, 11 after three days. There were nine autopsies, of which three died from pneumonia (which was described as being lobar pneumonia distinctly) three from hemorrhage from ruptured lungs, and three from ruptures of the spleen. As I considered no cases except those with autopsies, I cannot answer the question except to say that such symptoms as spitting of blood and a certain amount of respiratory disturbance were common in those cases I have studied. Those three who died from hemorrhage of the lungs were what might be called pneumonitis.

It was not my purpose to discuss the question of treatment of these ruptures of the viscera, but rather to call attention to the possibility of ruptures of the viscera complicating other injuries. We frequently see cases of compound fractures which need to be etherized and put up; and the question comes whether the operation shall be done then or in the future. In many of the cases there is distinct shock, and the idea I intended to convey was that in cases of doubt it is better to let them alone. I think we have good reason to suppose many of them get well; as Dr. Richardson said of ruptures of the kidney, that "he had not seen any of them die." I think that this is also true of other organs. In connection with what Dr. Whitney said, I remember distinctly one case in which there was a very small laceration of the kidney, and the wording of the autopsy was that the right kidney lay in a mass of blood and blood-infiltrated tissues, that some of this blood had penetrated beneath the capsule of the kidney and that free blood was found in the pelvis of the kidney. Possibly this was a case of rupture of the supra-renal capsule.

DR. WHITNEY: There was a case of injury of the pancreas at the Massachusetts General Hospital, and some necrosis of fat tissue existed. I should like to ask whether this was associated with any of these cases of rupture of the pancreas.

DR. DWIGHT: In Dr. Cushing's case there was no sign of it, and in the other case the death occurred rapidly from injury to other organs.

BOSTON MEDICO-PSYCHOLOGICAL SOCIETY.

H. C. BALDWIN, M.D., SECRETARY.

MEETING of February 17, 1897.

DR. HOCH read a paper on

A CASE OF ACUTE INSANITY ASSOCIATED WITH DEFINITE CHANGES IN THE INTERNAL STRUCTURE OF THE NERVE-CELLS.

The case was that of a young man who had had a previous attack of insanity characterized by the presence of the symptoms of acute maniacal excitement. In the present attack there were at first some maniacal symptoms, but during much the greater part of the attack the patient was dazed and frightened. The pulse was constantly rapid, the temperature was somewhat elevated, and he slept none. The attack

was one of unusual severity, and the patient died in 10 days. The diagnosis is in all probability a depressive phase of periodic insanity (Kraepelin).

The changes in the nerve-cells (all the cells in the cortex were affected) consisted in a complete disappearance of all the chromophilic substance; the cells at the same time often preserving well their outlines. Some cells had deteriorated further, and the cytoplasm had begun to break up. The nuclei also were altered, being more homogeneous than the normal, more deeply stained and more compact in appearance, often uneven in outline, and surrounded by a lighter ring. The same changes were found in the Purkinje cells and their nuclei. In the lower portion of the medulla oblongata the anterior horn cells were much less affected; the nuclei were normal, the cytoplasm in the cell-body showed only beginning changes, and in the protoplasmatic processes the chromophilic substance was well stained and discrete. Nissl's method was used.

Dr. Hoch maintained that changes like those described must be due to something extraneous to the cells themselves, and spoke of a poison as being the most likely cause. The interest of the case lies in the fact that in a case of so-called functional psychosis there are found definite changes in the nerve-cells.

Stained sections from the cortex of this case and from a normal brain were exhibited through the microscope.

DR. W. L. WORCESTER, of Danvers, opened the discussion by saying that the toxic theory, as the cause of a large proportion of mental disturbances, is gaining ground. Kraepelin classes katatonia among the toxic insanities. Van Gieson describes lesions similar to the ones in this case as due to toxic causes. He thinks these lesions pathognomonic, and would not admit the toxic nature of cases in which they do not occur. There is, in his opinion, a tendency for the same sort of poisoning to occur again and again with intervals of health. This he believes to be the case in epilepsy, which he holds to be, in a large proportion of cases, due to intoxication from the alimentary canal.

DR. ADOLPH MEYER, of Worcester, said that, since in Cramer's case the nuclei of the brain axis had not been examined, one could be in doubt as to whether the changes in the cells were really limited to the cortex. But Dr. Hoch's case leaves no doubt in this respect. He concurred with the reader as regards his clinical view of the case, and in the idea that the lesion was unusually marked. It remains to be seen whether Nissl or Van Gieson is right; the latter claims that all poisons produce similar changes, whereas Nissl found differences both in the character and in the localization of the cell-changes.

DR. P. C. KNAPP agreed that the toxic theory was a very probable explanation of the case. He asked if this could be a case of amentia or acute exhaustion psychosis; and if Dr. Hoch found changes in different parts of the cortex, involving different centres.

DR. NOYES asked if this could be a case of galloping general paralysis. Dr. Hoch replied that the brain changes would have been different; and besides there was no specific history.

DR. TUTTLE thought that Dr. Hoch was conservative as to the value of the changes that he had found, and asked if researches had been made and changes found in ordinary cases of disease, especially in cases with high fever.

DR. HOCH replied that the normal cell that was shown came from a case of septicemia.

DR. TUTTLE then said that similar changes had been found by Van Gieson in cases of sunstroke.

DR. TAYLOR remarked that Van Gieson states that the affected cells have a tendency to recovery in these toxic processes.

DR. HOCH, in closing said that while he did not wish to lay too much stress upon the toxic theory, there was a good deal of reason for speaking of it in this case.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

NINETEENTH ANNUAL CONGRESS, HELD AT
WASHINGTON, D. C., MAY 4-6, 1897.

FIRST DAY. — TUESDAY.

THE President, DR. CHARLES H. KNIGHT, of New York, delivered the Annual Address.

PRESIDENT'S ADDRESS.

Attention was called to several matters of current interest. A protest was made against carelessness in clinical work, especially with regard to the non-observance of antiseptic precautions. Lamentable consequences may ensue from a careless non-observance of those rules with which we are all supposed to be perfectly familiar.

Closely allied to this topic was that of antiseptics in general. In the wounds we are in the habit of inflicting, absolute asepsis may be impossible, and perhaps, in view of the perfect drainage usually secured, unnecessary. The story of the birth of antisepticism has very recently been modestly told by Lister himself. The application of the principles laid down by him banished hospital gangrene in a single day from surgical practice. Syme believed that amputation, rather than any attempt to save the limb, was the proper course to follow in all compound fractures of the leg. Putrefaction was universal, and yielded only to the introduction of carbolic acid, to which the Father of Antisepsis still adheres as the safest and most efficient antiseptic.

A spirit of wise conservatism has always characterized the work of this Association. It has not given its adherence to every passing fad. The premature announcement of new therapeutic measures which trial proves to be inert has taught us all a healthy scepticism.

The value of the laryngoscope in relation to the singing voice is another matter of timely discussion. It has at least corroborated knowledge acquired in other ways. Recent cases of laryngectomy have taught us that the voice can be developed after operation by means of the aid provided by the teeth, lips, palate, tongue, pharyngeal wall, nasal cavities and the skull bones. While there is no agreement as to all the elements concerned in the production of the singing voice, doubtless all the information given by the laryngoscope as to the position and movements of the vocal cords in tone formation has already been furnished by dissection of the larynx. The mirror does not show why, of two individuals with apparently identical vocal apparatus, one sings while the other cannot sing a note. Nor does it tell us why a singer of artistic temperament and acquainted with all the

technical knowledge of his art, fails to thrill us. Laryngologists are often embarrassed when asked to manage the case of some youthful aspirant for lyric honors to whom nature has denied those gifts essential to success, but an intense satisfaction is felt when a lost voice can be restored or such advice given as will assist in its recovery. In cases of vocal impairment, the mirror will enable us to determine with accuracy whether the condition be due to disturbed innervation, defect of muscular action, neoplasms, tissue hypertrophy or simple inflammation.

The discovery during the last year of the Röntgen rays bids fair to assist in our special line of work by locating foreign bodies, determining the size of tumors and in marking out the extent of malignant infiltration. Pride may be felt in the fact that one of the Corresponding Fellows of this Association, Dr. John MacIntyre of Glasgow, has successfully applied this new discovery to our special line of work.

Finally, it becomes us to approach with caution, and at the same time with candor, the matter of vivisection. As you all know, a bill is now pending in Congress, ostensibly merely to prevent cruelty to animals in the District of Columbia. No sane man can object to restrictions which look to the prevention of wanton cruelty; but we can have no patience with that sickly sentimentality which evokes spasms of maudlin sympathy over the death of a worthless dog and yet denies to suffering humanity hope of exemption from diseases, the study of which may most readily be conducted upon the lower animals.

The subject is one of importance to all scientific physicians. Who shall say that vivisection has accomplished nothing for humanity? Who can set aside the magnificent achievements of Harvey, Magendie, Claude Bernard and Pasteur? Even Morton, with all his courage, would hardly have dared to apply his beneficent discovery upon human beings without preliminary tests upon animals. Thus, without animal experimentation, the Jubilee of Anesthesia might not have been celebrated last year, and the human race might have long been deprived of that blessed immunity from pain which it has enjoyed for the last fifty years. We claim that vivisection is justifiable, and should be permitted as a means of impressing certain important facts upon the minds of students in our schools, not indiscriminately to a general medical class, but to the more advanced and special students in pathology and biology.

It is to be hoped that the good sense of our law-makers will enable them to act discreetly in the disposal of this matter, and to divest the question of the sophistries and calumnies associated with it by ignorance and prejudice.

DR. J. E. NEWCOMB, of New York, read a paper on

GUAIACOL AS A LOCAL ANESTHETIC IN MINOR OPERATIONS IN THE NOSE AND THROAT.

While cocaine answers in a general way the demands of an ideal local anesthetic, its use is not always free from unpleasant consequences. At times even alarming results follow. Various substitutes have been proposed. Of these latter those which have come into greatest favor have been tropococaine and eucaine. Latest reports of even these show that they are not entirely free from danger. Two years ago Lucas-Championnière suggested that guaiacol might

be used for this purpose. The first definite application of the remedy in laryngology was made by Laurens. He employed a five-per-cent. solution in olive oil freed from its albuminoids, resinous and coloring matters by means of dried sulphate of zinc, and from its free fatty acids by absolute alcohol. With the oil thus purified, guaiacol makes a clear, limpid solution. It may be employed as is cocaine in spray, by swabbing or on tampons.

Laurens's experience may be summarized as follows: In the ear, a few drops of the warmed solution can be instilled after previous cleansing, and in from fifteen to twenty minutes removed with hydrophile gauze. Sufficient anesthesia is thereby induced to enable paracentesis to be done in a painless manner. Similarly, furuncles of the meatus may be incised in the nose, after the usual tamponing or spraying, cauterization of the turbinates can be done without discomfort, polyps and polypoid tissue removed with the cold snare, and even the hot wire can be similarly employed. The tissues do not retract as with cocaine, so that guaiacol will never be its equal where we wish to systematically examine the nose, or in case of suspected neurosis make out the possible existence of sensitive areas. In the pharynx guaiacol may cause decided reflex movements, and yet sufficient anesthesia may be induced to cauterize granulations and enlarged tonsils.

Geronzi repeated with success the work of Laurens. He dissolved the guaiacol in alcohol, thereby making the remedy easier to handle while not modifying its anesthetic power. In the ear, he was able to puncture the drum, remove granulations therefrom, remove aural polyps and also the malleus, the anesthesia being perfect.

Dr. Newcomb had given the remedy a trial in 36 cases. It was used in spray, on tampons, by application and by the hypodermic needle. The operations done included removal of polyps and polypoid tissue with the cold snare, curetting of the ethmoid cells, sawing off of septal spurs, cauterization of turbinates and of enlarged tonsils, curetting the pharyngeal vault, etc. As regards anesthesia, it was perfect in 14, partial in 16, slight in two and absent in four. No more bleeding in the cutting operations was noticed than with cocaine, though guaiacol is said not to contract the tissues.

In the cases thus far reported, numbering 98 in all, no constitutional effect has been noticed. In order to obtain satisfactory anesthesia at least fifteen minutes must be allowed for complete absorption.

DR. S. W. LANGMAID, of Boston, read a paper on
SUB-MUCOUS HEMORRHAGE OF THE VOCAL CORDS.

Five cases were reported, three in men and two in women. All were voice users, four being singers, and one was an actor. In all, the site of the hemorrhage was at the junction of the anterior and middle third of the cord. In one, the extravasation was diffused, but in the remaining four, there was noticeable a globule of blood under the mucosa, as definite and distinct as the bubble in a spirit-level. All were due to vocal strain and presented a sudden onset with sudden hoarseness, vocal impairment and a limitation of voice in the higher register. In all there was accompanying catarrh. The clot was once on the left side and four times on the right.

The cause of this condition is to be looked for in the lameness of the phonatory muscles which necessi-

tates overstrain of them in order to bring the vocal bands into proper position. Congestion ensues, followed by rupture of the delicate vessels. This accident may happen in the best artists as well as in those who are victims of a faulty vocal method. In all, a cure ensued, with full restoration of voice. In one case, the clot disappeared in seventy-two hours.

An unusual thing in this series of five cases was that none of them presented any hemoptysis. The globular look of the extravasated mass of blood had not been mentioned by any previous reporters on the subject. Dundas Grant had reported a case showing a fluid tumor (hematoma), which came on after violent sneezing. As a rule, both cords were affected.

Treatment should consist of absolute rest, followed by local astringents. Meuthol sprays had been of service in Dr. Laugmaid's experience. Strychnine should be given internally, followed up by intra-laryngeal galvanization.

DR. J. W. GLEITSMANN, of New York, recalled one case due to a severe blow on the larynx. Hemoptysis had ensued, but the clot had finally disappeared. The late Dr. Morgan had reported one case of hemorrhage into the vocal bands.

The next paper was read by DR. A. COOLIDGE, JR., of Boston, on

HYSTERICAL DYSPHAGIA.

This condition was to be differentiated from esophagismus or gullet-spasm. It had occurred about once in every five hundred cases recorded in the Nose and Throat Clinic at the Massachusetts General Hospital. Women were more frequently affected than men, but the affection might be seen in children. Emotional causes and reflex disturbances were also causative factors.

The condition generally came on suddenly, and was attended with pain, a sense of constriction, and the feeling as of a foreign body. Globus hystericus might occur from an upward movement of the spastic segment of the gullet. Patients would emaciate, while regurgitation was rare. The sound might or might not pass readily. Auscultation generally gave negative results. There was often temporary abatement of symptoms. The obstruction was experienced in the first part of deglutition.

Treatment should consist in the frequent passing of bougies and the removal of any neighboring lesions. Suggestion might cure some cases. The electric bougie should be carefully avoided, as disastrous results had followed its use, probably from stimulation of the cardiac fibres of the vagus, thereby affecting heart action.

DRS. W. H. PARK, of New York, and JONATHAN WRIGHT, of Brooklyn, prepared a paper on

BACTERIA OF THE NORMAL NOSE, AND BACTERICIDAL PROPERTIES OF NASAL MUCUS,

which was read by Dr. Wright. Mucus was examined from 36 healthy noses. The vibrissæ were cut away, and the vestibule washed clean with a bichloride solution; sterilized cotton swabs were then rubbed over the deeper intra-nasal structures and inoculated into various culture media. In only six instances did the latter fail to develop colonies of bacterial growth.

The mucosa of the nose was examined in two rabbits, and bacteria were found in each instance. Nasal mucus in the human species was not bactericidal to the

germs of diphtheria or to staphylococci or streptococci but checked the growth of anthrax bacilli. The latter result also followed the use of sterilized sheep's serum.

Bacteria of a pathogenic nature were scarce in the deeper parts of the nares, owing to several causes. The vibrissæ strained the tidal air, which also contained but few pathogenic germs. The action of the cilia, the gravity force of the clear serous fluid from above where the tidal air did not penetrate, and the fact that nasal mucus was a poor culture media for most varieties, all contributed to the same result.

A drop of a virulent bacterial culture had been allowed to drop into each of the noses of two rabbits and both animals had died of septic infection inside of two or three days.

DR. J. W. GLEITSMANN, of New York, read a paper entitled

TREATMENT OF CHRONIC AFFECTIONS OF THE TONSILS, WITH DEMONSTRATION OF INSTRUMENTS.

Next to tonsillar hypertrophy the most frequent chronic malady of the tonsil is the chronic inflammation of its follicles. The surface of the organ becomes rough and irregular in contour, the follicles are destroyed, and the crypts plugged up with white masses, the products of inflammation, the retention of which is a common source of trouble. The plugs are frequently overlooked until the upper part of the tonsil is exposed with a palate-hook, when they are easily seen. It is in the latter place that the plugs most frequently accumulate.

Where the leptothrix deposits are present in the lacunæ Moritz Schmidt's blunt hook is a satisfactory instrument for raking them out. Its value is increased if the sides are sharpened.

Frequently the presence of a flap or fold of the tonsil prevents an inspection of its posterior surface. If a careful examination is made, it will be seen that this fold is not (as it might at first appear) a part of the anterior pillar. If the latter is drawn aside with a suitable hook, a small lymphoid deposit is seen between the two. The larger part of the tonsil is always found behind the fold. This condition probably results from a previous acute inflammation.

Dr. Gleitsmann exhibited a tonsil-clipper which he had had made on the general model of the Ruault forceps. It is, however, much smaller, and cuts in a horizontal instead of a vertical plane. When these folds are removed, it is better to use cocaine. If the fold is very large, it is better to operate at several different sittings. Bleeding is slight and easily controlled by cracked ice. In some cases it may be advisable to use some light caustic or styptic solution.

SECOND DAY. — WEDNESDAY.

INTRA-NASAL TUMOR.

DR. J. H. BRYAN, of Washington, exhibited a patient with an intra-nasal tumor which had been causing symptoms of nasal stenosis for the last four years. The patient was a man of twenty-two. The growth appeared on the left anterior naris and in the right posterior, having apparently eroded the septum. A bit had been examined and a diagnosis of fibro-sarcoma made. During the last few weeks he had had giddiness and double vision. There was no spontaneous bleeding, but the mass bled very easily on manipulation. Dr. Bryan asked for the opinion of those pre-

sent as to the most advisable method of operation in this case. He deemed it unwise to attempt the use of the snare, as a more radical operation was necessary.

Dr. J. SOLIS-COHEN, of Philadelphia, thought that the Rogue operation would answer.

Dr. J. N. MACKENZIE, of Baltimore, would advise the modified Langenbeck operation, whereby the superior maxilla was rotated outward and free access to the growth obtained.

REPORT OF A CASE OF SUPPURATIVE INFLAMMATION OF THE FRONTAL, ETHMOIDAL AND MAXILLARY SINUSES.

Paper by Dr. J. H. BRYAN, of Washington.

The clinical history was given in detail. The writer thought that frontal sinus disease was more common than is usually thought to be the case. Many cases are referable to the recent grippé epidemics. The frontal sinus disease may be primary and cause maxillary disease, or in some instances there seems to be an abnormal communication between the two sinuses, and then the disease can travel upward from the antrum to the frontal cavity. In general the so-called frontal affection is, in reality, fronto-ethmoidal. Recent examinations have shown that the infundibulum is frequently continued down beyond its natural point of stoppage at the hiatus semilunaris as a half-tube, at the end of which is a valve of mucous membrane acting as a guide to direct the discharge from above into the antrum. Dr. Bryan gave a full description of the frontal sinuses, exhibiting a series of photographs. He advocated the Luc operation, and had done it in this case. The drainage-tube running from the sinus down into the nose slipped and led to the retention of discharge, causing a mild sepsis which was quickly relieved by the restoration of full drainage. He would in the future always use a self-retaining tube. As an antiseptic he used 1-2,000 formalin solution.

Dr. W. E. CASSELBERRY, of Chicago, had been much dissatisfied with the results of intra-nasal treatment in these cases. The Luc operation offered a greater assurance of permanent cure and left no scar.

Dr. MACKENZIE would advocate under all such conditions the use of the mildest possible antiseptics. It had been shown that bichloride in solutions as weak as 1-10,000 would cause superficial necrosis of the tissues. Care should be also taken to avoid as much as possible the use of drainage-tubes. They were pus-producers and carriers of infection.

Dr. J. E. NICHOLS, of New York, thought that the appearance of pus would enable one to determine whether the antral disease was primary or secondary. In the latter the pus would appear as long, screw-like threads, while in the former it would appear as flakes or solid masses.

(To be continued.)

THE CARE OF BABIES IN PARIS.—A resolution has been submitted to the municipal council of Paris requiring families to furnish every two months a medical certificate stating that infants under one year have been cared for in accordance with hygienic rules. The efforts of the French government to increase the fighting strength of its army are an interesting spectacle, especially to the Germans.

Recent Literature.

Minor Surgery and Bandaging. Including the Treatment of Fractures and Dislocations; the Ligation of Arteries, Amputations, Excisions and Resections; Operations upon Nerves and Tendons; Tracheotomy; Intubation of the Larynx; etc. By HENRY R. WHARTON, M.D., Demonstrator of Surgery in the University of Pennsylvania, Surgeon to the Presbyterian Hospital, the Methodist Episcopal Hospital, and the Children's Hospital; Consulting Surgeon to the Presbyterian Orphanage. Third Edition, thoroughly revised and enlarged, with 475 illustrations. Philadelphia and New York: Lea Brothers & Co. 1896.

Dr. Wharton's "Minor Surgery" has reached its third edition, and additions have been made to it to enable the student to do operative work on the cadaver. The work is divided into the following parts: Bandaging, Minor Surgery, Fracture, Dislocations, Operations, Amputations, Excisions and Resections. In this latter division are descriptions of various special operations.

The book is well written, covers the ground of a Minor Surgery, but is open to the criticism that it does not deal explicitly enough with the detail of technical work. As Minor Surgeries are compiled, it is a very good one.

Elementary Bandaging and Surgical Dressing. With Directions concerning the Immediate Treatment of Cases of Emergency. For the Use of Dressers and Nurses. By WALTER PYE, F.R.C.S., late surgeon to St. Mary's Hospital. Revised and in part rewritten by G. BELLINGHAM SMITH, F.R.C.S., Surgical Registrar, Guy's Hospital. Seventh edition. Philadelphia: W. B. Saunders. 1897.

This little work has reached its seventh edition, and has been revised by G. Bellingham Smith. It is essentially a re-issue of those portions of "Surgical Handicraft," by Pye, which deal with bandaging, the application of splints, and the treatment of emergencies. It is intended to be useful to surgical house-officers and nurses. It is divided into three sections; the first dealing with apparatus for restraint and support (bandages, splints, etc.); the second treating of the simpler ways of dressing wounds, burns and scalds; and the third on the treatment of accidents and emergencies.

It is essentially an English book, and in it are many of the conventional forms of splints which the modern surgeon has long since discarded for the more readily adaptable plaster of Paris. The section on the treatment of accidents and emergencies is excellent. As a piece of book-making, however, it is crude.

Practical Notes on Urinary Analysis. By WILLIAM B. CANFIELD, A.M., M.D., Lecturer on Clinical Medicine, University of Maryland, etc. Second and revised edition. Detroit: George S. Davis. 1896.

There are at least two or three excellent text-books of moderate size devoted to the analysis of urine; and this one seems to us to be an unnecessary addition to the literature of the subject. It contains nothing of importance that cannot be found elsewhere, and is too brief in its treatment of the subject to be of any great value for either student or practitioner.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, AUGUST 19, 1897.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

POISONS IN ETIOLOGY.

ONE of the most significant advances of the past few years has undoubtedly been the attention paid to the importance of various toxic causes in the production of disease. The work of Van Gieson of New York and of many foreign investigators has forced upon us the conviction that the etiological problems, which are the real problems of medicine, may be much more intelligently met by broadening our conception of the idea of the poisons, and studying with every possible means at the disposal of our laboratories the chemical questions which such a conception involves. Not only may many diseases of the nervous system, among them the all-important one of epilepsy, possibly be elucidated by such means, as our methods of investigation improve, but other conditions of the internal organs, as, for example, certain varieties of renal disease, may well find a possible if not an absolutely demonstrable cause, in the action, over long periods of time, of poisonous products elaborated within the body, as a result of some subtly faulty metabolism.

Unquestionably progress lies in this line of investigation; and each and every case, whatever organ or set of organs may be affected, whose etiology suggests a poisoning of any sort should be studied with greater care than ever before, in the hope that finally we may be enabled to make generalizations of value. It is self-evident, as civilization advances and new products are used more and more in the arts and in our homes, that new dangers must of necessity arise, and a constantly growing list of so-called extrinsic poisons be brought into our daily life. The history of wall-papers and the probable deleterious effect of even small quantities of water-gas may be cited as examples of the dangers which may be surrounding us, and which are dangers until their recognition permits us properly to defend ourselves.

There can be no doubt that there are many such malign influences of which we have as yet no adequate

knowledge. The curious and interesting effect of certain poisons on the optic nerve is an excellent example of the tendency of such agents to lead to more or less serious degenerative processes. Examples of this sort are familiar to every ophthalmologist and are not infrequently met with in the course of general practice; such, for instance, as the amblyopias following the excessive use of tobacco or alcohol.

A case of rather unusual character, in this general category, has been recently reported by Dr. Archibald G. Thomson, at a meeting of the Philadelphia County Medical Society. The patient was a sailor, thirty-two years old, with unimportant previous history, excepting that several times a year he was in the habit of indulging excessively in alcohol; his use of tobacco was moderate; his eyesight had always been good until the onset of the present illness. On this occasion being unable to obtain the customary whiskey, he partook of a large amount of ordinary commercial Jamaica ginger, amounting in all to about a quart and a half. On the following day the man's feelings were similar to those that follow an alcoholic debauch, but much intensified. A day or two later he noticed that his vision was failing, with some photophobia. Two days later blindness was complete. At the end of seven days vision gradually began to return and recovery was complete in about four weeks. Matters remained thus stationary for three weeks, when vision again began to fail, but more slowly. Examination showed the discs to be exceedingly pale with an almost entire absence of capillaries. The lower and outer quadrant was completely atrophied and greenish-white in color. There were also somewhat remarkable changes in the visual fields. One of the patient's friends, who had accompanied him on his debauch, had a similar disturbance of vision though in less degree. Further questioning brought out the interesting fact that in certain localities the custom of drinking Jamaica ginger in lieu of alcohol is not uncommon, and that the patient had heard of several other cases similar to his own.

The case presents, therefore, several very interesting features:

- (1) The uncommon nature of the agent producing the poisoning.
- (2) The suddenness of the attack of complete blindness.
- (3) The peculiar changes in the fields which correspond most probably with the pathologic condition that takes place in the nerve.

In reply to a question addressed to Professor Remington of the Philadelphia College of Pharmacy, he wrote as follows:

What is known as Jamaica ginger, or more properly, essence of Jamaica ginger, is made in a very simple manner, by percolating the ground ginger-root with alcohol or alcohol containing water. The cheap trash found in country stores is often made with a portion of capsicum, in this way saving expense. You can see that a very little capsicum would take the place in pungency of a large quantity of ginger. Of course sufficient ginger would have to be used to give a flavor to the decoction. Then, again, it is made hot with cayenne pepper; a weaker alcohol can be used, and this would cheapen the product very much.

Dr. Thomson gives an interesting and reasonable explanation of the curious series of phenomena above noted, regarding the disturbance as due to a profound poisoning resulting in an acute retro-bulbar neuritis. After the seven days of blindness, as the neuritis subsided and pressure was at least in part relieved, vision gradually returned. The second failure of vision was a secondary atrophy.

If this explanation be correct, it is evident that certain poisons, of which Jamaica ginger is an unusual example, may excite an acute inflammatory process. This is of the more interest, inasmuch as we have ample evidence to show that many toxic agents act by producing a primary parenchymatous degeneration.

We cannot too strongly urge upon the profession the desirability of making as exhaustive a study as lies in their power of all cases in which a toxic agent may be suspected, as causative of the symptoms observed. If this be conscientiously done we may look for a distinct advance in our knowledge of the manifold etiology of disease.

MEDICAL NOTES.

CHINESE WOMAN DOCTOR.—The Siang-Hu Hospital in Foo Chow, China, is in charge of a Chinese woman doctor—Dr. Hu King Eng, who received her medical education in the United States.

LORD WOLSELEY HAS CANCER.—The report comes from London that Lord Wolseley, Commander-in-Chief of the British Army, is suffering from cancer of the throat, due, it is said, to excessive smoking.

A PATENT-MEDICINE MAN FINED.—An English patent-medicine manufacturer was recently fined \$260 at the Liverpool Assizes for painting an advertisement of his pills on the Hull of Lord Nelson's old flag-ship, the *Foudroyant*.

A MONUMENT TO VELPEAU.—A monument has been erected at Brèches, in the Department of Indre et Loire, to the famous surgeon Velpeau, who was born there on May 18, 1795. He was the son of a village blacksmith.

THE FOULARD LIBRARY.—The library at the St. Louis Hospital, Paris, founded by Dr. Foulard, the distinguished dermatologist, who perished in the Charity Bazaar fire, is to be named after him, and a subscription has been opened to collect funds to erect a bust to his memory.

WOMEN AS APOTHECARIES.—At the forthcoming annual meeting of German Apothecaries, which is to be held in Strassburg towards the end of August, the question of throwing open the trade to women is to be debated. The proposal will be as follows: Women are to be allowed to become apothecaries provided they are properly qualified, and provided that in each case the applicant seems of sufficient bodily strength.

THE HARDSHIPS OF HOSPITAL INTERNES IN PARIS.—The internes of the Salpêtrière Hospital, Paris, discontented with their sleeping accommodation, have

forwarded to the Director of Public Assistance a glass bottle containing a collection of domestic insects more agreeable by their absence than their presence, which can never be overlooked. This historic bottle bears the following inscription—"A crop gathered in our dormitory, 6-7 July, 1897."

THE CHOLERA SEASON IN INDIA.—Although there is a certain amount of cholera and choleraic diarrhea in Bombay and Poona, and a somewhat increased prevalence of these diseases at Sholapoor, it appears that the summer in India generally has so far been a healthy one as regards epidemic disease. Cholera, which threatened to be severe in the central parts of the country in the spring, has died out, according to the *Pioneer Mail*, except in the Deccan, and the plague has practically now ceased as regards its epidemic form.

THE INTERNATIONAL MEDICAL CONGRESS.—Telegraphing on July 30th from Moscow, the correspondent of the *London Standard* states that according to the latest lists nearly 5,000 members are expected to assemble in Moscow in August for the Twelfth International Medical Congress. Half of that number are Russians; Germany is sending 800, Austria 600, France about 500, and other countries average about 100 members. The Grand Imperial Theatre has been placed at the disposal of the Congress for the general assemblies.

THE ORLEANS-TURIN DUEL.—In the first "assault," what would be called "round" in the Anglo-Saxon vernacular, Prince Henri was wounded in the breast, but the surgeons reported that this wound did not "penetrate beyond the subcutaneous cellular tissue"; in the third the Count of Turin received the same sort of injury on the wrist, in other words devoid of euphemism, a scratch; in the fifth round Prince Henri received a wound which did "penetrate the subcutaneous cellular tissue," and which, "if it had gone deeper," would have caused a solution of continuity in the intestine. Prince Henri was declared disabled. The count, having inflicted this wound, is said to have hurried forward greatly agitated, exclaiming: "I hope it is not serious."

Notwithstanding a careful disinfection of the swords before the duel, the wound of the prince is said not to be healing satisfactorily. The report in the French papers that the count wore a coat of mail which caused the prince's sword to be bent has been denied.

Mr. Steve Brodie, of the Bowery, New York, is reported to have sent, at a cost of seventeen dollars, the following telegram:

To His Royal Highness, Prince Henri of Orleans, care of Duc de Chartres, Rue Jean Goujon, Paris, France:

Will give you and Gen. Albertone \$50,000 apiece if you will fight your coming duel before the kinetoscope, giving me exclusive rights to use of films. Will give you \$10,000 apiece additional if you will make the duel last for at least ten rounds.

STEVE BRODIE.

The duellists are still exposed to the danger of excommunication by the Pope.

CARBOLIC ACID AS A POISON. — We have alluded in these columns to the dangers attending the popular use of carbolic acid as a surgical dressing, and the necessity of the general diffusion of a knowledge of its dangerous properties. In Great Britain, at least this fact is being recognized, as shown in a communication addressed by Mr. Ernest Hart, Chairman of the Parliamentary Bills Committee to the Lord President of the Privy Council on July 1st, calling attention to the fact that the *Dublin Gazette* of June 18th contained an order from the Privy Council providing that, in accordance with a resolution passed by the Royal College of Physicians in Ireland, carbolic acid should be deemed poison in accordance with the provisions of the "Act to Regulate the Sale of Poisons in Ireland," and stating that the Parliamentary Bills Committee would be glad to learn whether they might anticipate a similar provision being shortly made in respect to England and Scotland. A reply has been received to this communication to the effect that a bill dealing with the subject is at present under the consideration of the government, and that pending its introduction in Parliament it is not proposed to include carbolic acid in the schedule to the Pharmacy Act, 1868.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, August 18, 1897, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 30, scarlet fever 23, measles 10, typhoid fever 41.

A RECOVERY FROM TETANUS UNDER ANTITOXIN TREATMENT. — A case of traumatic tetanus has recently recovered at the Boston City Hospital under treatment by antitoxin supplied by the Massachusetts State Board of Health.

A CENTENARIAN. — The one-hundredth anniversary of the birth of Mrs. Mary Curless Vickers was celebrated August 16th, in Oxford, Mass. Mrs. Vickers was born in Smithfield, R. I., and comes from Indian stock. Her father lived to the age of one hundred and one years. In Thompson, Conn., she married Samuel Vickers in 1814, and had eleven children.

NEW YORK.

DEATH OF DR. KROG. — Dr. Albert E. W. Krog, a well-known German practitioner, died suddenly of cardiac disease at his home in New York on August 10th, in the fifty-first year of his age. He was born in Germany, but studied medicine in this country, and was graduated from the Medical Department of the University of the City of New York in 1881.

THE DANGERS OF AMBULANCE SERVICE. — On August 13th there was a hurry call for an ambulance at the Harlem Hospital. A little girl had fallen from a second-story window and fractured her skull. Out started an ambulance in hot haste, carrying two physi-

cians; but it never got to the case. At the corner of Third Avenue and 125th Street it collided with a cable car, and was totally wrecked. One of the physicians, Dr. Rulson, of the visiting hospital staff, was hurled against an elevated railroad pillar, and received a bad contusion of the left side and arm, an abrasion of the right hand, and severe internal injuries. The other, Dr. Armstrong, the regular ambulance surgeon, got a dislocation at the hip-joint, and the driver was also badly stunned.

Miscellany.

BOSTON BOARD OF MUNICIPAL STATISTICS.

EDWARD M. HARTWELL, M.D.

DR. EDWARD M. HARTWELL has resigned the position of director of Physical Training in the Boston Public Schools in order to accept an appointment as Secretary of the Board of Municipal Statistics lately established.

Whilst in Europe last summer Dr. Hartwell, at the request of the Mayor, visited the principal municipal statistical offices and prepared a report which is now before us as Boston City Document 94, 1897. As the result of his investigations Dr. Hartwell concludes that:

Municipal statistics are more comprehensive, various and scientifically presented on the continent of Europe than is the case in Great Britain or the United States. The continental municipal statistical offices present certain characteristics, as a class, that are significant and noteworthy. (1) They are apparently independent and self-contained; (2) they are more closely connected with the executive and administrative departments of the city government than with any other; (3) they are organized as permanent scientific bureaus, under the responsible charge of highly trained specialists, who, by reason of their character, ability and standing, command the respect of their colleagues and of the public; (4) their jurisdiction is so well defined, and their work so systematized, that they accomplish a great amount of routine work and of independent research with a comparatively small staff of subordinate assistants and clerks; (5) their publications, being models in respect to comprehensiveness, conciseness and trustworthiness, are of more than local value, and are serviceable for the purposes of the comparative student of municipal life and development, be he sanitarian, politician, economist or sociologist.

The statistical offices of the leading German cities are so well organized that, through the co-operation of their directors, there is now published a "Statistical Year-Book of German Cities," which was established in 1891. This work contains a valuable series of comparative tables upon certain standard subjects of statistical inquiry, such as are contained in the statistical year-books whose rubrics I have enumerated; and from time to time special subjects of statistical interest are contained in this year-book.

It would be impossible, under present conditions, to publish a similar work for English cities or for American cities; yet both in the case of British and American cities, the public documents published by the various departments and bureaus of their respective governments contain a great deal of statistical matter. But statistical information concerning the various departments of city activity and housekeeping is now so scattered in the publications of our American municipalities that its value is materially diminished. It is manifestly in the interest of public policy that well-digested statistical tables, both of detailed

and summary nature, should be prepared by competent hands, and set forth in compact, convenient form for the information of city officials and the electorate.

The establishment by American cities of a statistical bureau, which would serve as a clearing-house for all their statistics, would conduce greatly to increasing intelligent interest on the part of the citizens at large in public affairs, and would also facilitate what is greatly needed,—the dissemination of accurate official statistical reports for the benefit of students of municipal and economic affairs. At present, persons who desire complete information concerning city finances, school affairs, vital statistics, etc., etc., for a period of years, are obliged to search in a great variety of documents for the data necessary to afford a comparative view of the development of municipal house-keeping.

It is especially noteworthy that the population statistics gathered and published by the municipal statistical offices on the continent are valuable and complete; much more so than is commonly the case with such statistics in this country. The fact that the census of cities like Berlin, Paris, Buda-pest, etc., are prepared by their respective municipal statistical offices under the direction of permanent and highly trained officials adds largely to their value. It is also noteworthy that statistics regarding movement of the population and the public health are much fuller, more detailed and valuable than those commonly published in this country. Not only are the vital statistics fuller, and more completely analyzed, but statistics regarding persons suffering from different forms of disease are more comprehensive than those usually found in the public documents which issue from American city offices. This is partly due to the more complete system of civil registration which obtains in all continental cities, but it appears to be also largely due to the fact that officials and the public are more interested in receiving complete and regular information concerning the ravages of death and the condition of the public health. The weekly, monthly and quarterly publications of most continental statistical offices present remarkably full and well-digested statements concerning morbidity as well as mortality statistics. The value of such statistics as a means to judging the condition of the environment of municipal population can hardly be overestimated. Reforms of far-reaching and permanent value have been instituted in several instances as a result of the mortality and morbidity statistics published by municipal statistical offices. The showing of the statistical bureau of Buda-pest, for instance, with regard to the amount of illness and death in low and ill-ventilated dwellings, has had a marked influence in causing reform and improvement in the building laws of that city. The studies of Director Böckh, of the Berlin Statistical Office, with regard to the comparative mortality of infants fed upon different articles of food are extremely interesting, and of great scientific value.

It is possible for a well-conducted municipal statistical office to render most valuable assistance to the heads of all departments of city affairs, as well as to enable the chief magistrates of cities to acquire ready and accurate information upon a great number of subjects of vital importance. A catalogue of the special independent studies, published separately from the regular publications of the statistical offices, which I have considered, would indicate the helpful character of such offices in acquiring and spreading information of a special character upon subjects which are usually left with us to private students.

In their aims, organization and achievements, the leading Municipal Statistical Offices on the continent of Europe betoken a more highly developed state of municipal life and organization than has yet been attained elsewhere. In the sphere of municipal administration such offices serve much the same purpose as does the "headquarters staff" in the administration of modern military affairs. That is to say, being organized as "intelligence departments," they furnish the executive department of the city government with such information as it requires for devising and conducting its plan of campaign against ignorance, disease, crime, pau-

perism and extravagance. Through their publications, such offices are also capable of rendering important aid to the electorate in arriving at intelligent conclusions as to the degree of fidelity and efficiency shown by its public servants in the discharge of their duties.

Experience has shown that city statistical offices, such as are described in the foregoing pages, constitute an important and effectual aid to the intelligent, practical and economical conduct of municipal business and housekeeping. The establishment by Boston and other great cities of the United States of similar offices could hardly fail to conduce to better government and a more enlightened public spirit, provided the teachings of the best European experience in this field were clearly apprehended and consistently applied in their organization and management.

PENETRATING WOUND OF THE HEART: RECOVERY.

RECOVERY from penetrating wounds of the heart is so rare, that the following case operated upon by Dr. Parrozzani at the Hospital of Santa Maria della Consolazione in Rome, and communicated to the *Lancet* of July 31st by Dr. G. Sanderson Brock, is of very unusual interest.

On the night of April 18th, a porter, age thirty-two years, of very robust constitution, received a stab from a dagger in the seventh left intercostal space in the mid-axillary line. Five hours afterwards he presented all the symptoms of excessive hemorrhage. There was evidently no time to be lost and he was operated on at once. An incision was made through skin and muscle commencing at about one and a quarter inches (three centimetres) from the margin of the sternum in the fourth intercostal space, along which it was carried for a distance of five and a half inches (fourteen centimetres). It was then continued at right angles to its former direction downwards along the mid-axillary line, including the dagger wound in its course, as far as the upper margin of the ninth rib. The pleura was next incised at the level of the fourth intercostal space and the fifth, sixth, seventh and eighth ribs, with the attached pleura, cut through in the vertical line. A triangular-shaped door or shutter, to which the costal cartilages acted as a hinge, was thus formed. The pleural cavity was found filled with blood, and the pericardium presented a wound one inch (two and a half centimetres) in length, from which at regular intervals issued a small jet of blood. The opening in the pericardium having been enlarged to nearly two and a half inches (six centimetres), the cavity was freed of the small quantity of blood it contained.

The blood had not accumulated in the pericardial sac in any very considerable quantity owing to the fact that the wound in the latter, being at its most dependent part near the apex of the heart, had allowed the blood to escape readily into the pleural cavity. This was a fortunate circumstance, since the usual cause of death in these cases—namely, the fatal pressure exercised upon the heart by the blood accumulating in the sac around it—was here absent. The apex of the heart presented a wound about three-quarters of an inch (two centimetres) in length, from which the blood spurted in small jets at every beat. The pulsations had become so extremely feeble that it seemed as if they were about to stop. Introducing the little finger into the wound, Dr. Parrozzani found

that it passed into the left ventricle obliquely, but quite freely from the apex towards the base. The inserted finger served the double purpose of checking the hemorrhage and of fixing the apex of the heart so that the wound could more easily be secured. A large curved needle armed with silk was now passed deeply through the whole thickness of the myocardium, but without touching the endocardium, the little finger being withdrawn from the wound and the thread rapidly knotted. The entrance of the needle into the myocardium caused the heart to throb vigorously, and the withdrawal of the finger was followed by a gush of blood completely flooding and obscuring the field of operation. The wound was, however, effectually closed by three more stitches, the blood-clots cleared out of both pericardial and pleural sacs, and the "sbutton" in the chest-wall closed. The operation lasted an hour and a quarter. No chloroform was used, but twelve subcutaneous injections of ether, and five of camphorated oil, and a few of caffeine were administered. A saline solution (1,500 grammes) was introduced by hypodermoclysis, and thorough auto-infusion (by means of Esmarch's bandages) was practised. One hour after the operation the pulse became quite perceptible. The wound healed by first intention, and no complication in myocardium or pericardium arose during convalescence. The temperature rose to 102° F., but this was probably connected with a slough which formed in the right pectoral region where the saline solution was injected. On May 26th, thirty-eight days after the operation, the patient had nearly recovered from his profound anemia, and said he felt quite well.

According to Professor Tassi¹ (in whose clinic four of them occurred) eight cases of wound of the pericardium or of the heart and pericardium have been operated upon in Rome during the last six years; of these, four involved the pericardium alone and four the pericardium and one or other of the ventricles. Of the former three were successful; of the latter two survived for only a few hours, one died after eight days from anemia, while the fourth—that related above—has proved entirely successful. There appear to be only two other cases recorded of the kind, where operative interference was attempted.

Dr. Parrozzani has since operated in a similar case—that of a young woman who was stabbed through the heart by another woman. The mode of procedure adopted was the same, the injury being again in the left ventricle. The patient, however, died on the second day, and on post-mortem examination it was found that the inter-ventricular septum had also been penetrated.

"COCK-MATRONS."¹

SUBSEQUENT editions of dictionaries of the English language will have to find space for a new compound word, namely, "cock-matrons." Possibly some of our readers will be curious to know whence this term originated. We will enlighten them. The term heads an editorial article, which appeared last week in a contemporary published in the sole interests of nurses, called the *Nursing Record*. This journal, as

is generally known, is conducted by a lady, who may be assumed to know something about matrons, inasmuch as she was once matron herself to a large general hospital in London. The article in question altogether disapproves of men having anything to do with the appointment or selection of the nurses at hospitals. "It has," says the writer, "been proved over and over again that man is rarely a competent judge of the capacities of women for work. Smartness, good looks, a taking manner, or a pretty bonnet have often turned the scale in favor of a candidate for a post when the appointment is made by men." Upon these grounds, then, "cock-matrons" must be condemned as impracticable hermaphrodite officials, whose judgment would always be certain to be biased and at fault. But perhaps the best way of dealing with this subject is to discuss the objectionable species of "cock-matrons" from a morphological point of view. It is then that the matter becomes very interesting, as those having a taste for morphology will soon discover. Upon the whole, however, we prefer to leave to our readers the pastime of working out for themselves the various problems which it suggests.

RECOVERY FROM A GUNSHOT WOUND OF THE UTERUS.

NEUGEBAUER, of Warsaw, reports in the *Münchener Medizinische Wochenschrift* for May 11th, a case of recovery after a gunshot wound of the uterus, which is remarkable not only in itself but on account of the various complications which ensued. A Polish woman, age thirty-four, who was in the eighth month of her eighth pregnancy received in the abdomen a charge of small shot from a pistol carelessly fired by her husband.

She was taken, bleeding freely, over twenty miles in a cart to a hospital at Czenstochau, where Dr. Wrzesniowski found a round wound in the abdomen, three inches above the pubes and a little to the right of the middle line, with a piece of omentum hanging out of it. The temperature was 103° F., pulse 120, and labor pains had set in. The fetal heart could not be heard, and there was found evidence of incipient pneumonia.

On opening the abdomen, a lacerated wound of the uterus was found, two inches below the insertion of the right Fallopian tube. Blood mixed with lochia and gas issued from it. An elastic ligature was passed around the uterus, and the fetus delivered through a longitudinal incision. On removal of the placenta, four small shot escaped from the uterine cavity. A diamond-shaped piece of tissue, including the gunshot wound, was cut out of the uterus, which was sewed up as in the ordinary Cæsarean section. An iodoform-gauze drain being carried down to Douglas's fossa, the abdomen was closed.

The fetus had been shot dead. The progress of the case at first was far from encouraging, as pneumonia and icterus developed, while the abdominal and uterine wounds both suppurated and broke down, so that the uterine cavity, full of pus, could be seen.

On the eleventh day Dr. Wrzesniowski amputated the uterus, passing two pins through the cervix, and treating the stump extra-peritoneally. Two months after the accident the woman returned home, and eight months later was in excellent health.

Correspondence.

AN INQUIRY.

GROVELAND, MASS., August 10, 1897.

MR. EDITOR:—I should be greatly indebted to any of your readers who would write to me concerning any experience they may have had in the use of goat's milk in the treatment of wasting disease.

I should also be very glad to receive at the same time professional opinion concerning goat-blood serum as to its antitoxic effect in the treatment of tuberculosis, diphtheria, etc.

In my opinion goat blood serum will be found a valuable agent in serum-therapy.

Very respectfully,

W. THORNTON PARKER, M.D.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, AUGUST 7, 1897.

Cities.	Estimated population.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from

Deaths reported 3,409; under five years of age 1,545; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping cough, erysipelas, and fever) 976, consumption 509, acute lung diseases 143, diarrheal diseases 794, diphtheria and croup 66, typhoid fever 53, whooping-cough 25, cerebro-spinal meningitis 15, measles 10, scarlet fever 10, erysipelas 3.

From whooping-cough Washington 7, New York 6, Brooklyn 4, Chicago, St. Louis and Boston 2 each, Cleveland and Cambridge 1 each. From cerebro-spinal meningitis Boston 5, New York 4, Washington and Worcester 2 each, Providence and Lynn 1 each. From measles New York 6, Brooklyn 4. From scarlet fever New York 5, Brooklyn 2, Chicago, Baltimore and Pittsburg 1 each. From erysipelas New York 2, Baltimore 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,392,524, for the week ending July 31st, the death-rate was 22.9. Deaths reported 4,827;

diarrhea 994, measles 143, whooping-cough 87, diphtheria 54, scarlet fever 37, fever 21, small-pox (London) 1.

The death-rates ranged from 9.9 in Croydon to 32.6 in Liverpool; Birmingham 27.0, Bradford 15.8, Bristol 15.4, Gateshead 22.7, Hull 16.2, Leeds 19.6, Leicester 21.3, London 23.6, Manchester 25.7, Newcastle-on-Tyne 15.8, Nottingham 22.8, Portsmouth 28.0, Sheffield 32.0, Sunderland 19.8.

METEOROLOGICAL RECORD

For the week ending August 7th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

CHLOROFORM IN OBSTETRICS.¹

BY EDWARD P. DAVIS, A.M., M.D.,

Professor of Obstetrics and Diseases of Infancy in the Philadelphia Polytechnic, Clinical Professor of Obstetrics in the Jefferson Medical College, and Medical Director of the Jefferson Maternity, etc.

IN accepting your kind invitation to contribute a paper upon this topic, I do not do so as an advocate for the exclusive use of chloroform in obstetrics, but as one who employs chloroform and ether, believing that each anesthetic has advantages which fit it for different but equally important uses. The grounds upon which I base the belief that chloroform is a suitable drug for the obstetrician are found in the action of chloroform itself, in certain peculiarities of the pregnant patient, and in personal experience. The prolonged researches upon the action of chloroform have recently culminated in the work of the Hyderabad Commissions and in other investigations which this has called forth. Experimenters have been divided into two great groups, one holding that chloroform, when used to produce death, does so from cardiac failure; while others believe that this result follows paralysis of the respiratory centres. If, however, laboratory tracings by many independent observers be examined, one common feature is present, namely, a striking demonstration that fall of blood-pressure is produced by chloroform. This was shown by Bowditch and Minot, Coates, H. C. Wood, Gaskell and Shore, the Hyderabad Commissions, Wood and Hare, and Hare and Thornton. Leonard Hill's investigations, in his "Physiology and Pathology of the Cerebral Circulation," showed the abdominal vessels filled with blood under chloroform anesthesia, the heart acting, but the medulla anemic and respiration paralyzed. This condition is further proven by Hare's experiments in the laboratories of the Jefferson College, when he found that in an animal apparently dead, resuscitation was possible by compressing the abdominal viscera, performing artificial respiration, and forcing the blood from the dilated abdominal vessels to the heart and brain by inversion. So far as experiment goes, Hare's conclusion in a recent paper² seems proven, namely, that the cause of death from chloroform is usually vasomotor depression.

Clinically, those surgeons who have been accustomed to employ this agent have learned that in cases of apparent failure of respiration that inversion of the patient, with compression of the abdominal viscera, and artificial respiration have repeatedly saved life. It has been noticed that many fatalities from chloroform have arisen when the patient was in a sitting posture, or semi-recumbent, when the blood readily left the cranial centres. Hill shows that abdominal compression revives the patient by sending blood to the heart, while saline transfusion is useless because a large quantity of fluid can be injected before the vessels are sufficiently filled to restore the circulation. The action of belladonna as a vasomotor stimulant, and bandaging the limbs diminish the risk of chloroform by preventing overdistention of the blood-vessels. The value of the respiratory condition as a symptom lies in the fact that respiration depends upon a normal blood-supply to the medulla, and that so soon as the medulla begins to

be anemic through vasomotor paralysis, this condition is announced by irregular or failing breathing.

If we consider the condition of the pregnant patient who comes into labor, we find that during her pregnancy vascular tension is greater than normal. Many researches show that pregnancy does not predispose to anemia, but to an increase in the total mass of blood. Hypertrophy of the heart of an eccentric variety is held by the majority of investigators to be present. During active labor, the abdominal muscles, the diaphragm and the uterus are intermittently active, and this results in a strong and intermittent compression of the abdominal blood-vessels. Blood-pressure is much increased during the pains, while the activity of the respiratory centre is naturally enhanced. In his recent Presidential Address before the Edinburgh Obstetrical Society, Ballantyne³ finds in these phenomena a reason for the remarkable immunity which pregnant and parturient women display to the unfavorable effects of chloroform. We have exactly those conditions present best adapted to counteract vasomotor paralysis which laboratory research shows us may result from chloroform anesthesia. Ballantyne has been able to collect but eight deaths during labor in cases in which chloroform was administered. Of these but two furnished autopsies, in one of which general emphysema of the lungs was found, and in the other a fatty heart. As sudden death in labor may happen without anesthetic, he does not think that chloroform can be proven to have been the fatal agent in the remaining six cases.

The advantages which those who use chloroform find in this drug are its small bulk, its rapid and pleasant action, its easy administration, and the usual absence of nausea and headache after its employment. In view of its peculiar merits and dangers, I believe it to be the duty of the obstetrician to differentiate between chloroform and ether, employing each in appropriate cases. Chloroform finds successful employment in spontaneous labor in women whose sense of pain is exceedingly acute. With these patients the pressure of the advancing head causes reflex inhibition of the uterus and reflex spasm of the pelvic floor and vaginal outlet. In extreme cases, such a condition can be overcome by surgical anesthesia with ether, and the use of forceps, but in many cases this condition is well met by the administration of chloroform to partial anesthesia. Enough to wet an area upon a handkerchief or a napkin as large as a half-dollar, if inhaled at the height of the pain, will remove the inhibition and reflex suffering, leaving uterine contractions to assume their normal strength, and greatly sparing the energies of the patient.

In a series of observations upon the influence of chloroform on normal labor, Dönhoff⁴ has shown by the use of Schatz's tokodynamometer that while chloroform inhaled to complete anesthesia temporarily arrests labor-pains and thereby lengthens labor, that when but a small quantity is taken, uterine contractions are practically uninfluenced. Spiegelberg, in his Text-Book, regards the transient narcosis produced by the skilful use of chloroform in normal labor as without influence in lessening labor-pains, and useful in sparing suffering and promoting dilatation. Schroeder regarded the light narcosis produced by a small quantity of chloroform as of the greatest advantage in normal labors. In these cases, the patient often dozes between the pains in what very closely resembles normal sleep.

¹ Read by invitation before the Obstetrical Society of Boston, March 16, 1897.

³ Scottish Medical and Surgical Journal, January, 1897.

⁴ Archiv für Gynäkologie, Band 42, Heft 2, 1892.

In normal labor when the head comes upon the pelvic floor and reflex stimulation of the uterus threatens precipitate expulsion of the head, the patient may be well controlled by anesthetizing her with chloroform, pushing the anesthetic to partial unconsciousness as the head emerges. The mother's mental condition is described by these patients as being one of partial consciousness when the voices of the nurse and doctor are heard, while sensation is for a moment abolished. The mother cannot recall the expulsion of the head, although she quickly rouses to the knowledge that her child is born. It is rare to witness greater relief to suffering than is afforded at just this stage of labor by such use of chloroform.

In transverse presentations, when the amniotic liquid has long since been drained away, and tetanus of the uterine muscle is present with threatened rupture, chloroform is most efficient. Its administration may be preceded by hypodermatic injection of atropine, and by brandy given by the mouth. It should then be carried to complete anesthesia, and the operator will find but little resistance from the uterine muscle in his efforts to turn the child. I recall a case in which the child had perished some hours before, and in which immediate version was imperative. A colleague attempted the operation while the patient was anesthetized by ether. Although the anesthesia was carried to a profound degree, the effort was entirely unsuccessful. I suggested the use of chloroform, and was asked to be responsible for its administration. Under its use, the version was readily done.

A similar condition of uterine tetanus is sometimes seen with retained placenta. In some cases, the placenta is fully or partly adherent; in others, hour-glass contraction of the uterus is present; while in others simple spasm of the uterine muscle is the complication at hand. With these patients, chloroform enables the operator to remove the placenta with the least possible resistance from the uterus. The anesthetic should be stopped as soon as the womb is empty, when uterine relaxation will not follow.

In eclampsia, chloroform plays a most useful part. It promptly controls convulsions, and furthers the dilatation of the os for rapid delivery. It is not claimed that cases of eclampsia may not be successfully treated under ether, but those who use chloroform in this condition greatly appreciate its rapid and efficient action. The majority of surgical opinion inclines to the view that chloroform is less irritating to the kidneys than is sulphuric ether.

A field in which chloroform plays an especially important part is that of examinations for diagnosis in deciding upon obstetric operations. Those who perform these operations readily appreciate the difficulty in selecting a given procedure in cases of contracted pelvis. Our inability to accurately measure the fetus *in utero* leaves an element of uncertainty, and obliges us to hesitate in relying upon pelvic measurements exclusively. To determine as clearly as possible whether labor can be induced successfully; whether the forceps will terminate the case to advantage; whether symphyseotomy is indicated, or whether abdominal incision is required, we must often fall back upon an effort to determine the proportionate size of fetus and pelvis. This is best accomplished by placing the patient in suitable posture, having her bladder and rectum emptied, and while she is partially anesthetized with chloroform, pressing the head of the fetus into

the pelvis while the examining hand within the vagina appreciates its descent, or failure to engage. Chloroform is here useful because it so readily overcomes the spasmodic contraction of the pelvic floor which a sudden examination often excites. It permits thorough palpation of the pelvis without discomfort to the patient. It is quite possible that bromide of ethyl or carbon dioxide will prove equally efficient, but in my experience chloroform for these cases leaves nothing to be desired.

The relaxing properties of chloroform have caused it to be feared by obstetricians, lest it provoke uterine relaxation and hemorrhage. That this danger is not fancy is unquestionably true, but to produce this untoward result chloroform must be pushed to profound anesthesia. It is questionable whether ether or any anesthetic carried to profound anesthesia does not favor post-partum hemorrhage. I can recall no case in which relaxation and hemorrhage could be distinctly traced to the continuous use of chloroform.

As an anesthetic for major obstetric operations, chloroform may be used to advantage in cases where bronchitis is a complication. I recall a successful Cæsarean section performed upon a patient recovering from grip and bronchitis, and under the influence of chloroform. There was no tendency to relaxation of the uterus or to bleeding. In patients, however, in whom bronchial complications are not present, ether is the anesthetic to be preferred for major operations. In labor complicated by pathological conditions of the heart, chloroform often relieves the patient's dyspnea in a remarkable manner. That it is superior to ether can scarcely be asserted in these cases, unless it be that in some it would provoke less bronchial irritation than would ether. As these patients frequently have subacute bronchitis with pulmonary engorgement, chloroform might be the better anesthetic in such cases.

Ether, however, is in my experience distinctly to be preferred in the use of forceps; here the obstetrician desires to further uterine contractions in every possible way. The delivery of the patient is often prolonged, and if chloroform is given to complete anesthesia, the uterus will often relax and the obstetrician will push the child's head away from the brim of the pelvis in his efforts to apply the forceps. This is especially true in cases where the high application of the forceps must be practised. For symphyseotomy, ether is preferred for the same reason, as these labors are generally terminated by the use of forceps. For embryotomy, ether is again preferable, except in cases where tetanus of the uterus threatens uterine rupture.

Another reason for preferring ether in the operations just mentioned is the fact that in most of these cases, namely, forceps extraction, symphyseotomy or embryotomy, lacerations of the cervix, pelvic floor, and perineum occur which demand immediate suture. This prolongs the anesthesia, and as the obstetrician's attention is demanded exclusively for his immediate work, he can much better employ ether with an assistant than attempt to maintain chloroform anesthesia. With the use of ether, these operations may be completed by suture of the genital tract with a minimum of risk to the patient.

The method of administering chloroform in labor requires care and watchful attention. The patient should be given an abundance of air with the anesthetic. In normal labor, the obstetrician may retain the chloroform-bottle in his possession, while the

nurse or helper holds the napkin or handkerchief above the patient's face. When it is desirable to give as little of any anesthetic as possible, chloroform may be diluted with cologne and the patient allowed to inhale this dilute mixture in small quantities with her pangs. The mental effect far outweighs the physical, but the result is often most satisfactory. My preference is for the Esmarch mask, a device which has been found to be most convenient and advantageous. From a half-drachm to a drachm of chloroform poured upon the mask is quite sufficient to control severe expulsive pains. Experiments teach us not to give chloroform unless the patient is lying down; to watch the breathing closely; and should this become in the least irregular, to instantly abandon the anesthetic; and should the patient not quickly recover consciousness, to practise compression of the abdomen and complete or partial inversion of the patient. I have never had occasion to do this, nor have I seen this necessity arise.

In the service of the Jefferson Maternity, chloroform is employed in the manner described by my chief clinical assistant and by the resident physicians, the anesthetic being commonly given by the chief nurse, the clinic nurse, or by the nurse on duty. The nurses are instructed in its use, and in the use of ether, by the chief clinical assistant. We have not yet had a bad result from its use, although it is my constant effort to impress upon the staff the fact that an anesthetic is a powerful and dangerous drug, to be invariably used with caution.

In the *Zeitschrift für Geburtshilfe*, Band 29, 1894, page 171, Strassmann contributes an interesting paper upon the use of chloroform in obstetrics and gynecology. He administered this anesthetic in over 20 patients who had valvular heart lesions, and operated upon them under this anesthetic. His observations agree with Bardeleben's⁵ in that neither observed the slightest disadvantage from the anesthetic. On the contrary, in obstetric cases Strassmann observed a most favorable influence from this drug. He prefers chloroform derived from chloral hydrate, as purest and best. He cautions against the exposure of chloroform to sunlight, as a partial decomposition results with the formation of irritating compounds. Binz⁶ has seen chloroform injured by frequent shaking, and believes that this may bring about an alteration in its composition. The atmosphere of the room where chloroform is given should be free from dampness, as the vapor tends to mix less readily with air, and is inhaled in a more concentrated condition. Strassmann, in common with Budin,⁷ B. et Coyne,⁸ Cullen,⁹ Dogiel,¹⁰ Storkowski,¹¹ Schiff,¹² Schlager,¹³ Vogel,¹⁴ Winslow,¹⁵ and White,¹⁶ lays great stress

upon the condition of the pupil as indicating safety or danger during the use of chloroform. These observations, however, have been supplemented by recent experiments already quoted, which lead us to watch the breathing of the patient rather than the condition of the pupil. The occurrence of vomiting was also formerly considered a symptom of considerable importance.

The return to consciousness of a patient who has inhaled chloroform is not furthered by disturbing the patient. Strassman very sensibly urges that such cases be left in absolute quiet so long as the respiration is deep and regular.

In the treatment of abortion, chloroform is especially useful in cases where spasmodic contraction of the uterus resists the effort of the obstetrician to thoroughly empty that organ. The paramount duty in these cases is to see that the uterus is clear and empty, and in securing this result chloroform is especially useful. Its relaxing effect upon the uterus enables the physician to explore the uterine cavity with comparative freedom. In my experience, it has proven especially serviceable in these cases.

When it is necessary to interfere with the pregnant uterus in the induction of labor, chloroform is useful in those patients who resist all manipulation so that the introduction of a bougie is a most difficult proceeding. It is undesirable with these patients to put them under complete anesthesia whenever a bougie or an elastic bag is placed within the cervix. In these chloroform again fulfills a useful purpose. In dilating the uterus in the pernicious nausea and vomiting of pregnancy, unusual difficulty is often experienced. In many of these women the cervix is in a pathological condition, being abnormally thick and resisting, and a state of extreme spasm being present and complicating any manipulation. Severe pain, accompanied by great depression, is often observed in these patients. When it is necessary to stretch the cervix or to empty the uterus, chloroform has been most useful in my experience.

The obstetrician is occasionally greatly embarrassed in the conduct of labor among the insane. Such women often manifest little sign of suffering, and give no information regarding the presence or progress of active uterine contractions. At the moment when the child is expelled, they are often exceedingly hard to manage, becoming maniacal, and frequently sustain injury from excessively strong uterine contractions. To control these patients, I have found chloroform of great advantage.

The effect of anesthetics administered to the mother upon the fetus is a subject of much interest. Usually the fetus does not seem to share the mother's anesthesia unless this has been prolonged and deep. So far as my observation goes, I have been able to detect no difference in the effect of ether and chloroform administered to the mother upon the fetus. It is difficult to estimate this, as in cases of prolonged delivery birth-pressure may produce asphyxia and partial coma which might be attributed to the anesthetic employed. Some of the most profound asphyxias which I have seen in the fetus have been in cases where the mother was delivered under the use of ether.

In conclusion, the following propositions may be advanced regarding this subject:

that the evil effects of chloroform result from vasomotor paralysis, causing the accumulation of blood in the abdominal viscera especially, and bringing about partial or complete cessation of function in the nervous centres from acute anemia.

(2) Pregnancy increases vasomotor tension, and thereby renders the pregnant woman less liable to the injurious effects of chloroform.

(3) In normal labor, the actual expulsion of the child may be safely rendered painless, dilatation of the birth-canal furthered, and laceration diminished, by light and transient narcosis from chloroform.

(4) In tetanus of the uterus, eclamptic convulsions, and maniacal labor, chloroform is to be preferred to ether, and is most useful.

(5) Profound narcosis from chloroform is seldom, if ever, necessary in obstetric practice, and like this condition under ether, is attended with risk.

THE SUPERIORITY OF CHLOROFORM AS AN ANESTHETIC IN MIDWIFERY PRACTICE.¹

BY A. WORCESTER, A.M., M.D., WALTHAM, MASS.

Not long ago, when returning the visit of a recent graduate from one of the best medical schools of this country who had the temerity to settle in this vicinity, I was asked if it is true that it will not do for a physician hereabouts to use chloroform in his midwifery practice. He had been warned by a previous caller that if he did use chloroform he would forfeit the support of the medical fraternity. Of course, it was understood that the forfeiture of professional support would be felt only in case of some awkward coincidence. But as accidents will sometimes happen, and as scapegoats are troublous animals if not thoroughly understood, it is well worth while to examine this particular chloroform scapegoat.

Granted that in this part of the world there has been a peculiar susceptibility to the poisonous effects of chloroform such as to preclude its use hitherto in midwifery practice, what, then, are the geographical limitations of this unfortunate inheritance, and must it last forever?

Such questions, while of little or no interest to physicians whose opinions upon this subject have long since been crystallized, are nevertheless interesting to those still open to conviction. For instance, my young friend already quoted, who has been taught by a most distinguished obstetrician that he should use chloroform, and just how to use it, very naturally is anxious to know how far it is advisable to disregard this local idiosyncrasy. He is entitled to all the information that can be gleaned from the experience of his new-found brethren.

So far as my own small experience goes, I have already assured him that for the past ten years, at a distance of ten miles from ether's shrine, chloroform has proved itself infinitely preferable to ether in relieving women from the agony of child-bearing. Unfortunately for my present argument, I have not used pure chloroform so often as I have used a mixture² of it with ethyl bromide and alcohol. I have to thank Dr. Walter J. Otis, of Boston, for calling my attention to

this mixture, which I still think superior even to chloroform in the rapidity of its anesthetic action without sacrifice of consciousness. But this difference is not great, and there is some difficulty in obtaining and in keeping absolutely pure ethyl bromide. So it not seldom happens that I use plain chloroform in midwifery practice. But if by any mischance I have only ether at hand, I feel a sense of shame akin to guilt. For many a time, when my chloroform vial has been drained of its last drop, and I have tried to hypnotize the patient into being thankful that at last she can have lovely ether, have I witnessed her disappointment and disgust. Instead of the instantaneous relief that came from a few deep inhalations of the chloroform, the patient on changing to ether finds that she no longer has time or strength, after the earliest intimation of a coming pain, to inhale enough of the anesthetic to do her any good. As the stress of suffering is upon her she keeps gasping at the ether when she should be holding her breath and so giving to the abdominal muscles a fixed thorax to pull from. The usefulness of the labor pain is thus lessened. If she has been steadily inhaling ether during the pain, then by about the time it is over she will be more or less under its influence. Possibly she may sleep during the intervals, but she is more likely to thrash about begging for more ether. There is little use in assuring her she is not just then in pain; her answer is unanswerable, that she soon will be, and then it will be too late to get any good from the ether. If she is smart enough she will simulate a pain so as to scare the etherizer into putting it on before the real pain begins. "Give me more! give me more!! GIVE ME MORE!!!" prevails, and her pains are effectually relieved. Then the end is within plainer sight.

You all know the rest of the story, and can vouch for this synopsis of it: gradual cessation of labor pains; complete exhaustion; mother's pulse 120; fetal heart 160; paternal pulse fluttering; consultant sent for to hear the pitiful story; operative interference plainly demanded; because high forceps and version are equally dangerous, first one method is timidly tried and then the other; perineum torn to sphincter, but fortunately no further; complete relaxation of uterus and of everything else; alarming post-partum hemorrhage skilfully treated by manual extraction of the placenta and plugging the uterus with iodoform gauze; bruised fetus resuscitated after a half-hour of artificial respiration; tedious convalescence, but eventual recovery; all concerned more than ever convinced of the wonderful blessing of ether in midwifery; "What did our poor grandmothers and grandfathers do without it?"

If by good chance the laboring woman, in disgust that the ether does her no good, tosses the mockery from her and in her indignation pulls all the harder, then it must be admitted the ether has done no harm. Moreover, in midwifery cases where prolonged surgical anesthesia is required, ether of course has its proper place. But where only partial anesthesia is desirable, ether is a delusion and a snare. Once begun, either it is found to be useless, or if given in serviceable amount the labor is delayed if not absolutely stopped, and all the trouble of artificial labor thus inaugurated.

Small wonder is it that many physicians here in this ether district so dislike to employ the only anesthetic they know anything about, that they actually deliver

¹ Read at the meeting of the Obstetrical Society of Boston, March 16, 1897.

² Ethyl bromide, one part; chloroform, three parts; alcohol, four parts.

most of their patients without any anesthesia. Such physicians steel their hearts by making much of the increased safety so obtained. But were they themselves to suffer the pangs of child-bearing, it is doubtful if such beautiful fortitude would be displayed.

I must not, however, forget that my purpose in this paper is not to describe the use of ether in midwifery practice, but rather to call attention to the superior advantages of chloroform.

In the first place, then, it produces partial anesthesia much more quickly than ether, and with less loss of consciousness, and allows a correspondingly quick recovery from the anesthesia. Not only does chloroform itself act much more quickly, but it can be taken more quickly than ether, because of not irritating the respiratory apparatus, as ether is so liable to do. With chloroform there is none of the choking and coughing that so often retard ether anesthesia.

Let us for simplicity's sake consider the requirements of an ideal anesthetic during only the second stage of labor. In the first place we shall all agree that the anesthesia is desirable only during the height of the pain, that is, during the latter part of it, and is not wanted during the intervals. Moreover, after the pain begins, there is time only for a very few deep inhalations before it is necessary for the patient to apply all of her strength to her work. And, furthermore, the patient's intelligent co-operation is needed in securing the proper application of her voluntary muscular powers.

So closely do the properties of chloroform conform to these desiderata that it might seem as if the requirements of the case and the properties of this anesthetic were especially designed for each other. No such mutual fitness can be shown in favor of ether.

Now, with such a blessing at hand, is it fair to womankind to withhold it from them? Should the unsatisfactoriness of ether prevent the use of a really satisfactory anesthetic?

If there is any other excuse for not easing these pangs with a few whiffs of chloroform, that excuse is probably to be found in the local idiosyncrasy, to which reference has already been made. Whatever its cause, there undoubtedly is thought to be in this neighborhood a peculiar susceptibility to the supposed poison of this anesthetic. Had ether been discovered in Edinburgh and chloroform anesthesia given its first public demonstration in Boston, perhaps there would not be here such an acute form of chloroform-phobia. But, however that might be, is not this semi-centennial era of thanksgiving for anesthetics a very proper season for inquiring if it be possible, even in Boston, that chloroform now at this end of the century can be used in midwifery practice as safely and as advantageously as it is used everywhere else in the civilized world.

Let us admit that for prolonged surgical anesthesia ether is much less likely to cause the patient's death on the table; and let us waive the question, on the other hand, as to the after-effects of ether being more dangerous than those of chloroform; and let us leave out of consideration the great advantages of the use of chloroform at the beginning when ether is to be used later for maintaining the anesthesia; let us keep strictly to the question of partial anesthesia, repeatedly produced, for the relief of the second stage of labor sufferings. Will any one who has had experience with both dispute the immense superiority of chloro-

form? Or will any one maintain that there is any danger whatsoever in the proper use of it for this purpose?

In studying the origin, the extent and the probable duration of the local prejudice against chloroform, I must admit having wondered if dense ignorance as to its proper use deserves consideration as a potent factor. At any rate one need have no hesitancy in referring to this local ignorance, for, as is well known, it is not only generally admitted but is even considered a badge of distinction. Never to have given chloroform except to dogs whose deaths were desired is considered in this vicinity rather as a proof of virtuous conservatism than as a marked deficiency in professional attainment. It is pathetic to think of how many Boston blushes have been wasted at seeing chloroform used in every other part of the world by men who really seemed in other matters to know what they were about.

If it should seem that those poor medical graduates who are doomed to practise in New York or in other outside regions ought to be taught how to use chloroform, even if warned against using it hereabouts, the folly of so thinking is easily shown; for how can the proper methods of administering chloroform be taught where none is used?

The hope of persuading others to make a fair trial of chloroform in such cases, and the hope of drawing from our guests suggestions as to the best methods of administering it, overcome the hesitancy that I, who have had no instruction in the matter, very properly should have in describing my methods of giving chloroform to women in labor.

Before ever the labor begins it is often of no small advantage to be able to answer the prospective mother's anxious question if I surely will give her an anesthetic by assuring her that I always do. Again, when in the wearisome first stage of labor the certainty that when the hard bearing-down pains begin the anesthetic will be given cheers the patient on as no other possible assurance could. For often it is in the fear that the pains will grow much harder that the greatest torture lies. American women suffer fearfully in anticipation. When the second stage is fairly begun, and the pains are really strong, then I begin with the chloroform. The patient's nose and lips are well smeared with vaseline to protect the skin from possible chloroform blistering. Upon the centre of a handkerchief or some such piece of cloth five to ten drops of chloroform are dropped just before the pains begin. At first the patient herself is taught to hold the cloth over her nose and mouth while inhaling deeply; but as her labor progresses and she becomes well used to it, the cloth is better held by the assistant who measures out the chloroform.

In the relief from the intensity of suffering thus obtained the patient becomes more willing to exert all her strength as directed. She wastes no time in "holding back" her pains; she escapes nervous exhaustion. As the perineum dilates, and as the suffering becomes continuous the chloroform is kept on more of the time; but after every few inhalations the cloth is taken off for a like number of inhalations of fresh air. By pouring on a few drops of the chloroform at almost every such interval, the patient is kept sufficiently anesthetized to escape the agony and at the same time is not made unconscious. In this condition the perineum often can be kept on its natural

stretch long enough to allow the delivery without rupturing. Her uterine and other muscular contractions are not interfered with. The mother just knows when her baby is born, but she remembers no especial pain. She does not afterwards live in terror of ever again going through the same experience.

THE USE OF ETHER IN OBSTETRIC PRACTICE.¹

BY CHARLES M. GREEN, M.D., BOSTON.

IN opening this discussion of "The Comparative Value of Ether and Chloroform in Obstetric Practice," it is best that I should state at the outset that I have had no experience whatever in the use of chloroform. It seems evident, therefore, that I am ill fitted to discuss a subject with which I am only partially familiar. I have been asked, however, to present concisely the way in which I use ether in obstetric practice, leaving to those who believe chloroform to be the better anesthetic the task of proving their position. This I am willing to do; especially since the burden of proof, in this community certainly, rests on those who would use chloroform instead of ether to produce anesthesia.

In stating my method of using ether in routine obstetric practice, I cannot do better than to quote from a paper I had the honor to read before the Boston Society for Medical Improvement four years ago.²

THE QUESTION OF ANESTHETICS IN NORMAL LABOR.

"In approaching this subject it is well to bear in mind that parturition is a physiological process, and physiological processes ought not to require the assistance of anesthesia. While willing to admit that modern woman is not perhaps the physical equal of her prototype, I am not prepared to grant that she is so degenerate as some writers would have us believe. The changed conditions of modern civilization have certainly wrought some changes in womankind; her nervous organization is not perhaps in many instances so stable and unimpressionable. It is a question whether the modern, higher education of women does not make demands upon their nervous systems which render them less able to bear without anesthesia the shock and pain of maternity. Be this as it may, I am not yet prepared to range myself with those who regard the use of anesthetics a necessary accompaniment of labor. Not that I believe, by any means, that woman should bear the curse of Eve, and submit to the pain of labor as an hereditary punishment; but because I believe that, as a rule, a girl with a healthy mental and physical inheritance, who has been well brought up, who has been well managed during pregnancy, and who approaches her labor in good condition, does not *need* anesthesia. Having said this much I hasten to remark that I am always ready to administer anesthetics on any reasonable indication, and do, in fact, employ them in moderation in many normal cases, partly to gratify the imperious demand, in the face of no contraindication, and partly for other reasons which will be stated later.

"During the first stage of normal labor it is only exceptionally that I find anesthesia either necessary or demanded by the patient. If this stage is well man-

aged, if the patient is well fed, and her attention properly diverted, she generally passes through the stage with equanimity and composure. If the stage is protracted, if the soft parts are unduly rigid, if the patient is decidedly hyperesthetic, if, in short, the labor is no longer normal, the indications must be met with appropriate therapeutics. Chloral hydrate is the drug, *par excellence*, for needed anesthesia in this stage, administered in fifteen-grain doses, at half-hour intervals, until three doses have been given, if necessary; the effect is satisfactory, and not injurious, if the heart is not weak. I usually give the drug by rectum to avoid disturbing the stomach, which may be already affected with the physiological nausea often seen towards the end of the stage.

"When the cervix is approaching the full dilatation, if the pressure of the passing head on the cervical ganglia causes undue pain, I then resort to ether, administered during the contractions. The amount given is not enough to inhibit the action of the uterus, but still enough to obtund the sensibility of the nerves and greatly comfort the patient. I never allow a woman in labor to bear pain which can be called in any way pathological.

"When the head has passed the cervix and the os has receded, the pain is usually less severe. The patient becomes conscious of progress, she is encouraged and looks forward to the birth of her child. She is cheered to make full use of her pains and brings to bear the material assistance of her voluntary muscles. If within two hours she has not brought the presenting part to the outlet, I cease to regard the case as normal, and employ such interference and assistance as may seem advisable. Otherwise I encourage the patient to make full use of her pains without anesthesia, until the head bulges the perineum, when I begin the administration of ether. This I give moderately at first that I may not diminish the effectiveness of the uterine contractions; but as the head crowns I push the ether, and deliver the woman under full surgical anesthesia. I do this for two reasons: first, because this brief use of ether does no harm, does not paralyze the uterus nor interfere with its retraction; secondly, because with the patient under full anesthesia I am better able to control the expulsion of the head and avoid laceration of the perineum.

"To state once more and in other words my position in regard to the use of ether in labor, I would say that while I am ready to use the anesthetic in the way and manner above described, I believe that the prolonged use of ether, even when not pushed to surgical anesthesia, is liable to inhibit the uterus and retard the labor; further, to interfere with efficient retraction of the uterus and predispose to hemorrhage; again, to etherize the child, and perhaps, in conjunction with a prolonged labor, to result in a still-birth. In short, my way is to soothe the patient with ether, if need be, through the peculiarly painful period when the head is passing the os uteri; then to subject her to a short, sharp labor, not exceeding two hours, and giving surgical anesthesia when the head is born. If after two hours of good labor the child is not born, nor apparently soon to be born naturally, I interfere. I believe that under this management the patient avoids one of the possible causes of post-partum hemorrhage; that she makes a better convalescence; that there is less risk of fetal mortality."

As to the method of administering ether, — I have

¹ Read before the Obstetrical Society of Boston, March 16, 1897.

² *See* Boston Medical and Surgical Journal, May 11, 1893.

always employed a towel-cone, and I have used preferably Squibb's ether. When only partial anesthesia is desired, I generally allow the patient to hold the cone and I myself pour on the ether. For surgical or complete anesthesia, in normal cases and in those requiring short, minor operations, I etherize the patient and then give the cone to the charge of a trained nurse, being careful to watch the patient's color and respiration myself, while the nurse observes the pulse. In major operations, I always avail myself of a trained medical assistant, competent to take the responsibility of the anesthesia. Thus far I have never met with disaster from the use of ether, and have never been seriously concerned for my patient, in obstetric etherization.

Death ensues from chloroform anesthesia from five to ten times as often as from ether narcosis. In view of this fact, let us briefly examine the advantages claimed for chloroform as an anesthetic agent.

(1) Chloroform is non-inflammatory and non-explosive, is less bulky, and a smaller amount is necessary to produce anesthesia.

The inflammatory and explosive quality of ether warns us to be careful in its use: I have never seen an accident from the ignition of ether. The comparatively larger bulk of ether may be of consequence in military field surgery; but in civil practice this is of small moment.

(2) Chloroform produces anesthesia more quickly, more agreeably to the patient, and there is less struggling.

It is probably true that chloroform does produce anesthesia more quickly; but it is also true, I think, that a skilful etherizer will, although generally taking a longer time, anesthetize his patient without causing much discomfort or any struggling. In obstetric etherization, the patient is generally allowed to etherize herself, and she becomes unconscious peacefully and without a struggle.

(3) Recovery from chloroform anesthesia is more prompt, the after-effects are less marked and there is less vomiting.

These advantages are, as far as I know, indisputable; but if the patient has been properly prepared for ether, vomiting is not usually a matter of much consequence and often does not occur at all, if atropia has been given. In obstetric practice the post-partum anesthetic sleep affords the patient a grateful rest.

(4) Chloroform causes less salivation and less irritation of the respiratory tract.

This is probably true. More or less profuse bronchial and salivary secretions sometimes give to the etherizer considerable trouble; and it is undeniable that bronchitis has sometimes apparently been caused by prolonged etherization. In marked cases of pulmonary disease, I would, if possible, avoid using ether; indeed I have occasionally operated without anesthesia in such cases. But as far as my knowledge goes, the danger to the lung from ether is trifling compared with the danger to the heart from chloroform. Whatever risk there is to the lung in the use of ether warns us to be extremely careful in its use, and shorten its administration as much as possible.

(5) Chloroform has a less injurious effect on the kidney.

While I am unprepared to speak with knowledge of the effect on the kidney of ether, I understand that in supposedly healthy kidneys ether sometimes causes

albuminuria, and that blood and casts are occasionally found in the urine after etherization; but I also understand that these phenomena are transitory, and disappear in a few days. In cases of chronic renal disease, it is generally conceded, I believe, that ether may cause serious harm. If ether is used in such cases, it should certainly be used sparingly. Whether the risk to the kidneys from ether would warrant us in taking the risks of chloroform, I hope to hear demonstrated this evening.

NASAL OBSTRUCTION WITH REFERENCE TO AURAL DISEASE.¹

BY GEORGE A. LELAND, M.D., BOSTON.

To be attributed to obstructed or neglected nasal respiration are not only deformities of the lower part of the face and of the chest, diseases of the teeth, of the mouth and of the eye, but also many of those of the upper air-passages, including the naso-pharynx, and last but no means least of the ear. Of the affections of the latter organ of special sense in this category those most commonly met with are diseases of the middle ear of a catarrhal or inflammatory nature.

Since the discovery of adenoid vegetations in the naso-pharynx by the late Dr. Wilhelm Meyer, of Copenhagen, in 1868, these growths are probably most commonly considered the cause of nasal obstruction; but since the nose has been opened up to us by the discovery of the anesthetic and constricting properties of cocaine in 1886, it has been found that hypertrophies of the nasal mucous membranes, exostoses, enchondromata and deflections of the septum nasi, not to mention nasal polypi, are also large factors in nasal obstruction.

The principal function of the nose is respiratory, that is, the modification of the inspired air by warming, moistening and straining so that it shall not be irritating to the mucous membranes of the air-passages. That it may accomplish these purposes it is essential that the lumen of the nares shall be free and unobstructed. If this normal condition obtains, the air-currents are free and full and no undue air-pressure, positive or negative, exercises any evil influence. But if because of trauma or improper development (Roe²) one or both nares become more or less obstructed, a partial vacuum is produced behind the obstruction, which, acting like the dry cup, tends to produce a hyperemia which also, as it is more or less chronic, results in a thickening—a hypertrophy or hyperplasia according to its chronicity or the kind of tissue involved. For example, in the soft succulent tissues of early childhood, attempts at nasal respiration, during a cold which has occluded the nose, doubtless bring about a hyperplasia of the naso-pharyngeal tonsil; and this is a very probable factor in the etiology of adenoid vegetations. So also an anterior obstruction of one naris causes a negative pressure behind it and hence a deflection of the septum, as shown by Mayo Collier.

In later life the thickened mucous membrane of the naso-pharynx may be due to the persistence of this

¹ Read before the Massachusetts Medical Society, June 8, 1897, and recommended for publication by the Society.

² Transactions of the Eighteenth Annual Meeting of the American Laryngological Association, p. 207, *et seq.*

hyperemic condition through the habit of mouth-breathing then established, and seldom corrected; or may be brought about by the same *modus operandi* through partial or complete obstruction caused by hard or soft growths in the nose. This growth or thickening in the naso-pharynx interferes with the proper action of the ventilator of the middle ear, the Eustachian tube. The movements of swallowing, which are more or less constant throughout the twenty-four hours, by means of the actions of the levator and the tensor palati muscles, should so open and close the Eustachian tube that air may be allowed to enter the middle ear, and the secretions of the tube and the mucous cavities beyond may be pumped out, as it were. The tensor palati sends a small band of muscular tissue up into the soft anterior wall of the tube; its name, the dilator tubæ (Rüdinger), describes its function. The levator palati, attached to the posterior and inferior border of the Eustachian cartilage, when in contraction throws a fold of mucous membrane upward horizontally so as to partially close the mouth of the tube, at the same time stretching its floor; and then by its relaxation exercises a pumping action. That the sulcus behind the Eustachian cartilage (fossa of Rosenmüller) should be open and clear, and the mucous membrane around and especially below the Eustachian os should not be too thick, seem to be necessary to the proper results of the performance of these muscular movements.

The direction of the intra-nasal air-currents is also found to be important. It has been said that the floor of the nose is the continuation of the Eustachian tube outward, and that the air-currents should play directly backward upon the mouth of the tube. That this is not strictly true may be concluded from the observations of Braune and Classen, Goodale and others, which have shown that the air entering the nasal orifices which look downward and slightly outward passes upward, forming whirls and eddies having horizontal axes and so passing through all the meatuses and reaching all parts of the nose. But that this inferior meatus should be patent is nevertheless proved in practice, since it doubtless exercises much influence on the condition of the Eustachian tube, as well as on those catarrhal states of the nose itself characterized by the retention of viscid mucous secretions which are irritating to the surfaces with which they come in contact.

The subjective symptoms of these causes of nasal obstruction, more or less complete, are:

(1) A feeling of pressure in the ear, as if it were plugged. If the Eustachian tube can no longer admit air through it, because of its own collapse or because its mouth is occluded by growths or thickening, the air in the middle ear loses 21 per cent. of its volume by absorption of its oxygen. The atmospheric pressure here at the sea level being fifteen pounds to the square inch, there would be a pressure of more than four pounds upon the membrana tympani provided the vacuum behind it were complete. But it must be remembered that the membrana tympani is almost the only movable part of the walls of the tympanum and all the air spaces communicating with it, including the antrum and other pneumatic chambers of the mastoid process, which may contain a large amount of air. If the oxygen of all this air, therefore, cannot be replenished, it is evident that the pressure-feeling has sufficient reason for its existence. This sensation may also be due to abnormal contact of two surfaces in the

nose itself, where it is doubtless reflex, as is frequently shown by its cessation when this contact is abolished.

(2) Deafness due to fixation of the ossicles from simple pressure upon the membrana tympani. This is but an aggravation of the process just described, made more effective by continuance of the external pressure or increase of its force. In these cases in early stages, both the pressure-feeling and the deafness may be temporarily relieved by inflation, but it is evident that the relief must be only temporary unless the patency of the Eustachian tube is restored.

(3) Tinnitus aurium. This is a symptom of such varied kind and quality that it is difficult to speak of it with positiveness; but it is doubtless true that often the pulsating, throbbing, hammering tinnitus is due to one or more of the lesions under consideration, the most evident of which is a mass of adenoid vegetations or of hypertrophic membrane in the fossa of Rosenmüller. The cartilage of the tube seems to act as a telephone to communicate the sounds of the circulation in the dilated arterioles to the organ of hearing. When these lymphatic structures are hyperplastic, it is probably true that similar glands in the vicinity are also hyperplastic or at least hyperemic, so that those imbedded in the tissues of the side of the pharynx and in the anterior and inferior walls of the Eustachian tube also send the sound of their aggravated circulation upward through the dense cartilaginous walls to the ear. Moreover, when these glands are increased in size, especially by chronic thickening, the ascending pharyngeal artery which runs in the side wall of the Eustachian tube, and sometimes nearer than others, may be pressed upon so as to have the sound of its pulse wave also communicated to the ear. These three causes of pulsating tinnitus are without doubt frequently operative; and it sometimes seems equally sure that an engorged turbinate may produce reflexly the same symptom, but the writer is not yet quite ready to make this assertion.

The hissing tinnitus is more difficult to locate. It is usually considered to be a circulation sound, and is probably most frequently attributed to the capillary circulation in a collapsed Eustachian tube; of course we are not now speaking of the noise when due to disturbances of the internal ear, or to inflammatory conditions around the footplate of the stapes. That this tinnitus may be due to the presence of a spur in the nose or to its pressure on neighboring structures sometimes seems to be the case, though it is difficult to prove; but the removal of such a spur is justifiable for this reason and the immediate cessation of the tinnitus is not to be expected.

(4) Pain is rarely a symptom of the slow, insidious closure of the Eustachian tube from the causes now under consideration, but is frequently met with in cases where stoppage is brought about by congestions in the nose and naso-pharynx consequent on colds, irritation of dust or bacteria, or other noxious influences which induce increased functional activity of the intra-nasal structures. Thus in childhood when the naso-pharyngeal space is relatively small, as shown by Dwight, a very slight swelling of the adenoidal growth is sufficient to close more or less completely the inner end of the Eustachian tube and so abolish ventilation and drainage. This is especially true when these growths are situated at the side of the naso-pharynx, notably in the fossa of Rosenmüller itself. And it may be confidently asserted that earaches in childhood

almost always occur as a result of the presence of adenoid vegetations — the exceptions being those reflex earaches from dentition and from tonsillitis, and those caused by trauma, and the invasion of micro-organisms.

In the adult a hyperemia of the diffuse lymphatic thickening, sometimes called lateral pharyngitis, or of the hypertrophic mucous membrane itself, may cause pain in the same way; and the affection of the middle ear in this early stage is sometimes designated by the name otitis catarrhalis simplex. A persistence of these conditions brings us to the next symptom:

(5) Effusion, in which a pain of considerable severity, lasting but a few hours, is followed by marked deafness and feeling of fullness with sometimes peculiar subjective sounds as of crackling paper or the succussion of fluid on quickly moving the head in certain directions, which sounds may often be heard by the observer through the diagnostic tube. Patients suffering from these effusions, which may be mucous but are usually serous, so constantly have also obstructive lesions of the nose and marked thickening of the mucous membrane at the side of the naso-pharynx that these latter conditions must be looked upon as the mechanical causes of the middle-ear affection.

A further aggravation of this symptom, as the persistent increase of the effusion, together with the continuance of the stoppage of the Eustachian tube, must result in the sixth symptom, namely,

(6) Discharge from the external meatus because of rupture of the membrana tympani, the discharge being usually serous at the outset and not becoming purulent unless contaminated with pyogenic micro-organisms from without.

And it is here submitted that these three latter symptoms, namely, pain, effusion and discharge through rupture of the membrana tympani, may be due to purely mechanical causes at the outset, being simply the results of the dry cupping in the vacuum produced by abolition of ventilation; though as hyperemia gives place to effusion, this is succeeded by inflammation, soon aggravated by the invasion of pathogenic micro-organisms ever waiting to rush in hosts to a field favorable to their destructive work.

The limitations of this paper preclude an exhaustive elaboration of these subjective symptoms, and hence they are but briefly considered as dependent on nasal obstruction *per se*, and not upon those affections caused by invasion of bacteria through the Eustachian tube. And it will not be necessary to allude to objective symptoms, since they may be inferred from what has been said; but there is one at least which it may be of service to describe, and that is the appearance of the membrana tympani. In cases where the tube is collapsed or mechanically closed by naso-pharyngeal obstruction this membrane is sunken, of a dark dull bluish color, showing no translucency since there is no air behind it, the manubrium is foreshortened, the short process is prominent, and the light reflex is either abolished or present usually as a minute bright point. This appearance is so constant as to be pathognomonic of this naso-pharyngeal condition, and might be designated as the adenoid ear.

TREATMENT.

The only rational deduction from what has been stated above is that treatment must be directed to the restoration of the proper ventilation and drainage of

the middle ear, and that the functions of the Eustachian tube must be restored. To this end causes of the obstruction of its mouth must be removed. Adenoid vegetations should be taken away, not only from the vault and the middle of the naso-pharynx, but from the sides, and especially from the fossæ of Rosenmüller — a point often omitted in cases operated upon simply for correction of the evils of mouth-breathing; and many a case of persistent deafness aggravated by colds, and of persistent purulent discharge from the ear may be apparently cured, at least so far as these two symptoms are concerned, if proper attention is given to this region. So also in later life thickening of the mucous membrane of the naso-pharynx should be reduced by suitable applications.

But the causes of these naso-pharyngeal conditions should receive their proper attention. Proper nasal respiration should be established; the habit of mouth-breathing corrected; obstructions to nasal respiration removed, to wit, deflections of the septum straightened, spurs and tumors removed, and hypertrophies reduced. By this is not meant that every structural peculiarity demands surgical interference. It is not necessary that the nose should be made anatomically perfect. This is often impossible. But that it should be put into such a state that its physiological functions may be properly performed; and that its air-currents may maintain their proper directions, is evidently essential. And here it should be laid down as a law, that at the expense of the hard parts all this should be accomplished if possible, since the tissues of the soft parts are especially adapted to the preparation of the air for respiratory purposes; and it might even be called malpractice to destroy or remove a lower turbinate when the cartilage of the septum may be altered in any way to establish the proper calibre of the nostril.

If a decade ago the efficacy of this line of treatment had been extolled and so much claimed for it as has been implied, it would probably have been thought chimerical. But as nasal treatment has been so much advanced in the last ten years, it has come into the experience of every aurist that simple inflation of the ears by the Politzer air-douche or even by the catheter leaves much to be desired.

The almost universal statement in the books that chronic middle-ear catarrh of the so-called dry, adhesive variety can only be watched, or treated so as to retard the process and perhaps keep the hearing where it is, is erroneous because, as a matter of fact, it has been abundantly proved that with a normal Eustachian tube every use of the handkerchief is more or less efficacious for inflation of the middle ear, and that the opening of the tube by every swallow is sufficient to keep up the equilibrium between the intra-tympanic air and the external atmosphere. And this leads in conclusion to the thought that the intra-nasal obstruction and abnormal contacts resulting in uncomfortable sensations of the nose, prompt the patient to use the handkerchief to excess; and when this is done in futile forceful efforts to remove fixed obstructions, the increase of pressure upon the membrana tympani often causes so much stretching of that delicate membrane as to preclude good results from subsequent attempts at treatment to restore the hearing. Thus frequently a patient presents himself for deafness showing a drum-head stretched in its upper posterior segment and almost invariably, also, a nose which has more or less obstruction in one or both nostrils.

RUPTURES OF THE VISCERA AND THEIR CONNECTION WITH SURGICAL SHOCK.¹

BY EDWIN WELLES DWIGHT, M.D.,

Surgeon to Out-patients, Boston City Hospital; Assistant in Legal Medicine and Clinical Surgery, Harvard Medical School.

(Concluded from No. 8, p. 174.)

RUPTURE OF THE STOMACH AND INTESTINES.

POLLOCK, in Holmes's "System of Surgery," says: "Perforation of the intestine, that is, rupture of the intestinal coats, the result of external violence without external wound, is by far the most frequently formidable injury with which the surgeon has to contend in practice. From the commencement of the duodenum to the termination of the sigmoid flexure of the colon, in any part of the whole length of the intestine, rupture of the entire wall does constantly occur from sudden violence, or passive forces applied to the front or sides of the abdomen." That rupture of the intestine is more common than rupture of the stomach, which is rather rare and probably never occurs unless that organ is distended, is the opinion of all authors; but that it "constantly" occurs, is not borne out either by autopsy records or clinical experience. The intestine is most liable to rupture when it is distended, and the lesion usually takes place in the jejunum or ileum; the ruptures may be single or multiple; may be, as in Case 5, simply superficial ruptures of the peritoneum or, as in Case 19, multiple and of considerable size. Death may result within a few hours from hemorrhage or, as is more commonly the case, after a period of from two to seven days from peritonitis.

Rupture of the stomach is less common than that of the intestines, and is usually the result of severe external violence upon a distended viscus; it is apt to be followed by considerable hemorrhage, and death within a few hours, as in Case 6, in which the large amount of undigested food would show that the stomach was distended at the time of the accident.

In a few rare instances in which the opening in the stomach wall is small, life may be prolonged until death ensues from peritonitis. These cases must, however, be rare, as, while the possibility is spoken of by various authors, I have found none such reported.

RUPTURE OF THE BLADDER.

Rupture of the normal bladder, the result of external violence without injury to the overlying structures, is said by all writers to be rare: when it does occur it may rupture into the peritoneal cavity and death follow from peritonitis, or the urine may be discharged into the cellular tissue, when the same chain of symptoms follows as in the more common ruptures of the urethra.

These two varieties are well shown in Cases 13 and 14, in both of which the duration of life was the same, five days, but death resulted from very different causes.

RUPTURE OF THE LUNGS.

The position of the lungs in the chest does not appear to offer the protection which it might be expected to; on the contrary, the armor of the ribs is often the weapon that is turned against them. But aside from those cases in which the lungs are punctured by the broken ends of the ribs, there are many in which rupture of the lungs occurs without injury by the ribs; Cases 1 and 2 are of this sort, for while in both there

were broken ribs, in neither were they so placed as to have caused the injury to the lung which was found.

Ruptures may occur in the lungs without any external sign of violence. All parts of any lobe are liable to rupture, and the severity of the lesion varies as it does in other organs. Contusions of and hemorrhages into the lung substance are common, while simple lacerations of the pleura are found; in extreme cases one or more lobes may be completely macerated. The amount of hemorrhage varies from the slightest ecchymosis to several pints. In the cases which I have examined, serious ruptures of the lungs have in every case been associated with injury to other organs.

RUPTURE OF THE HEART.

While rupture of the normal heart from external violence without external wound is rather a rare condition, quite a large number of such cases have been reported.

In 50 cases taken from various sources, I find that the right ventricle was ruptured in 17, the right auricle in 9, the left ventricle in 8, and the left auricle in 16. In about one-half of these cases the pericardium was apparently not injured.

In Case 6 a superficial rupture of the pericardium was found, which might have been made by the end of a broken rib, as the fourth rib was broken on the left side at its costal margin.

In Case 1 there was a rupture of the pericardium, of the intra-ventricular septum, and a superficial one of the heart's muscle near the apex. In Case 2 the pericardium was intact, and contained seven ounces of blood; there were ruptures of the right auricle and the auricular septum. Both of these cases were associated with injuries of other organs.

CONCLUSIONS.

So that we find upon making some study of the literature of the subject and examining the cases which accompany this paper, that ruptures may occur in any or all of the viscera, that they may be of all grades of severity, and that they may result from external violence without external sign that would lead one to suspect the conditions which lay underneath.

All of these lesions of the various organs, in all their degrees of severity, have one result, which they present to a greater or less degree in common, that is, hemorrhage.

Death in all cases, except in those which, like the intestines, bladder and heart, may result fatally in a way peculiar to themselves, comes as a result of that hemorrhage.

We have every reason to believe that the amount of hemorrhage depends upon the organs involved, and the extent and location of the rupture.

The symptoms of hemorrhage are the symptoms of "shock," and a "shock" is a term which is applied to these symptoms when there is no known condition to account for them.

"Shock," to a greater or less extent, is present in nearly every case after those common accidents which, as has been shown, not infrequently result in ruptures of the viscera.

A very considerable number of cases die during the course of a year, in our large hospitals, in which no autopsies are made, with but those indefinite terms "shock" or "multiple injuries" to account for these deaths. In those cases in which an autopsy is done,

¹ Read before the Boston Society for Medical Improvement, March 22, 1897.

after such a clinical diagnosis, there is always some condition present to account for the death.

If it be true that in any considerable number of cases, this group of symptoms is due to hemorrhage from injury to one or more viscera, it is of the greatest importance that such patients should be treated for concealed hemorrhage and not for "shock." The administration of ether, with its stimulating effects and the amount of struggling and restlessness consequent upon it would be contraindicated.

It has been my habit to subordinate the treatment of the local condition (as in compound fractures and other injuries of that class) to that of the general condition, even if the degree of shock were very moderate; and I feel confident that by so doing little harm has been done, and lives have been saved.

The following series of cases is reported as illustrating the great variety in which ruptures may occur in the various organs, both as to their character and location; the accidents which result in such conditions; the cause of death; and the possibility of recovery.

Cases 1 to 15 inclusive have been put into my hands by Dr. F. W. Draper for this purpose, all of them having occurred in his practice as medical examiner; and Cases 20 and 21 have been recently under the charge of Dr. H. W. Cushing in his service at the Boston City Hospital. It is through the courtesy of these gentlemen that I am able to report so large a number. The others were chosen from a rather large number which are to be found in the records of the Boston City Hospital.

Rupture of the Liver,	Cases 1, 3, 4, 5, 6, 7, 8, 9, 10, 11, 16, 17, 18.
Rupture of the Kidneys,	Cases 1, 9, 11, 12, 18, 20, 21.
Rupture of the Spleen,	Cases 6, 8, 12.
Rupture of the Pancreas,	Cases 10, 11, 21.
Rupture of the Bladder,	Cases 13, 14.
Rupture of the Stomach and Intestines,	Cases 5, 6, 15, 19.
Rupture of the Heart and Pericardium,	Cases 1, 2, 6.
Rupture of the Aorta,	Case 19.
Rupture of the Lungs,	Cases 1, 2, 4, 5, 6, 7, 8, 12, 17.
Rupture of the Pleura (ecchymoses),	Case 19.

CASE 1. Male, thirty-eight years. Fell from platform, twenty feet, striking on timbers, then in the mud. Lived twenty minutes.

Autopsy, Dr. Draper. Abrasions on left forehead, eyebrow, tip of nose, upper lip, chin, both sides of sternum between second and third ribs; and two teeth broken. Fractures: compound fracture of both bones of left leg, fracture of sternum, fracture of fifth and sixth ribs, not penetrating the pleura. Heart: rupture of pericardium from apex four inches upward; pericardium contained four ounces of fluid blood and considerable recent clot; old pericardial adhesions, with calcareous deposit; small superficial tear of heart's muscle at apex; rupture of inter-ventricular septum. Lungs: did not collapse; extravasation about pericardium; subpleural ecchymoses over both lungs, especially between the lobules. Peritoneal cavity contained about two ounces of red fluid. The right kidney lay in a subperitoneal effusion of blood; close upon the pelvis were four or five lacerations, one or two lines in depth and one-half inch long. Liver: at the inferior surface of the right lobe, near anterior edge, were a series of superficial abrasions; no effusion of blood into liver.

CASE 2. Male, forty years. Fell from wagon which was heavily loaded, and was run over. Lived about half an hour.

Autopsy, Dr. Draper. Large and muscular. Abrasions of both hands; on anterior aspect of left forearm, near the right margin of the sternum, just below nipple line, were three or four minute points of excoriations, size and shape of a grain of rye. No other sign of injury to the thorax. Heart contracted; pericardium contained seven

ounces of fluid and clotted blood; laceration of the right auricle on its anterior-superior wall, with irregular ragged edges that admitted the tips of three fingers; the auricular septum had a tear half an inch long in front of the fossa ovalis, and the thin septum closing the fossa was torn near its anterior edge. Lungs: small laceration in left lung, adjacent to that in the auricle; eight or ten small vesicles on each lung; containing air; universal injection and edema; bronchi contained pinkish froth like that in drowning but coarser; one subpleural ecchymosis at the inferior edge of right lung. Abdominal organs normal, except for injection of kidney and liver.

CASE 3. Male, adult. Assaulted. Lived thirty-three hours. Marked shock, pain in abdomen, persistent vomiting.

Autopsy, Dr. Draper. Ecchymoses of both eyelids. On opening abdomen a quantity of thick dark port-wine-colored fluid escaped, and at the same time a similar fluid escaped from the anus. Liver: gall-bladder distended with fluid "the color of molasses and the consistency of syrup"; inferior aspect of liver contused; in the substance of the liver were several clots each the size of a pullet's egg and of irregular shape; hepatic tissue pale, soft, and the vessels filled with dark fluid blood. There were 48 ounces of fluid blood in the abdominal cavity, the point of escape from the liver being "at the left border of the gall-bladder, near its insertion in the liver."

CASE 4. Male, sixty-six years. Accidental fall from third-story window. Lived nearly two hours.

Autopsy, Dr. Draper. Abrasions on left chest, between nipple and sternum; ecchymosis over right anterior-superior spine of ilium; blood oozing from right ear. Fractures: compound fractures of right clavicle, and dislocation of its outer end; all of the ribs on the right side broken, and muscles infiltrated with blood. Pleural cavities contained bloody serum, the left four ounces, and the right eight: posterior aspect of right lung torn, and tissue filled with a mass of clotted blood. Abdomen contained six ounces of bloody fluid. Kidneys showed beginning interstitial nephritis. Liver pale. At various points in the upper and under surfaces the liver substance is ruptured, the deepest being on the upper side of the right lobe where the depth reaches a quarter of an inch.

CASE 5. Female, thirty-two years. Lived two or three hours. Jumped out of third-story window.

Autopsy, Dr. Draper. Body small and spare, superficial bruises on left elbow and right shin; no other sign of injury. Fractures: left ulna, near elbow-joint; sternum; ribs (right 1, 2, 3, 4 and 12—left, 1, 2, 3, 4, and 7); spine; first lumbar and twelfth dorsal; spinal cord somewhat bruised and dura torn. Lungs showed a few small ecchymoses, most marked on posterior portions of right lung, which was firmly adherent to chest-wall. Ecchymoses on meso-colon and at the left of bladder. Peritoneum lacerated at four points in the large intestine, the largest being two inches by three-quarters of an inch in size. Liver lacerated superficially on upper anterior surface of left lobe; deeply and extensively on lower portions of the same lobe—of stellate form, the deepest being towards the transverse fissure where the tissue is much torn up. In the "pouch," at its extreme lower part, were two minute points of hemorrhage, each the size of a millet-seed. The inferior petrosal sinus was plugged with a firm, dark-colored clot.

CASE 6. Male, twenty-four years. He was driving a hack which was struck by a train. Lived fifty minutes.

Autopsy, Dr. Draper. Small bruises over lower third of sternum; two scalp wounds. Fractures: left femur in lower third; left humerus just above elbow; fourth rib near costal margin; compound depressed fracture of skull, with fissure into the middle fossa, some fluid over-spreading right hemisphere, considerable laceration of brain tissue. Heart: superficial rupture of pericardium. Lungs: about four ounces of blood in right pleural cavity, and at the base of the lower lobe of left lung was a considerable ecchymosis. Abdominal cavity contained 80 ounces of mingled blood and undigested food, the latter

in large amount. Stomach nearly empty; in anterior wall, at juncture with esophagus, reaching upward two or three quarter-inches, was a rupture involving all of the coats; at two points near the pylorus were superficial rents in the peritoneum. Liver: several linear superficial ruptures in its upper surface, and in the lower a number of deep ones; one in portal fissure posterior, and another at anterior edge of left lobe were very deep and ragged. Spleen "crushed, appearing as a mangled mass of shapeless fragments." Other organs pale and anemic.

CASE 7. Male, thirty-six years. Was in a small boat, run down by a steamer and struck by the paddle-wheels when in the water. Great collapse.

Autopsy, Dr. Draper. Bruises on outer side of left arm, below left nipple, above ensiform cartilage, on outer side of right thigh, inner side of right knee, on left back below angle of scapula. Fractures of right ribs (4, 5, 6 and 7). Posterior mediastinum much ecchymosed. Lungs: much ecchymosis posteriorly. Abdominal cavity contained 32 ounces of fluid blood. Liver: fracture extending from a point near the broad ligament posteriorly 11 inches, to the right border near the right kidney, leaving only the capsule as a hinge inferiorly, numerous secondary rents at each side of the main fracture, very ragged.

CASE 8. Male, fifty years. Struck, knocked down and run over by a wagon. Lived one hour and a half.

Autopsy, Dr. Draper. Bruises: over the crest of the right ilium was a very faint ecchymosis, the size of a silver dollar; no other sign of bruising. Lungs normal except for slight bruising at the root of right lung; considerable bruising of tissues near aorta in the posterior mediastinum, also of upper surface of diaphragm. Fractures of ribs (right, 4, 5, 6 and 7; left, 3, 4, 5, 6 and 7). Abdominal cavity contained 58 ounces of liquid blood. Spleen extensively ruptured, the rents being entirely in the upper portion and well away from the hilus; anteriorly there were five irregular and unequal tears in the capsule, all connecting with the substance; posteriorly the organ was wholly disorganized, being torn and ragged in all directions, especially towards the right border; the upper end of the organ was completely torn away from the rest. Liver: superficial wound on central inferior face two inches long and one-quarter inch deep; at left border or base was a rupture of the liver tissue not opening the peritoneum; here the organ was much broken up, and a considerable amount of blood effused into the tissue.

CASE 9. Male, thirty years. Struck in side and knocked down by horse-car. Condition of great shock; pulse thready, skin pale. Lived twelve hours.

Autopsy, Dr. Draper. Very fat. Bruises: very faint one over right eye and nose; outside of right nipple, size of palm of hand; some indistinct bruising of left flank. Fractures: ribs 3, 4, 5 and 6 on right, and 9 and 10 cartilages on left. Abdominal cavity contained two quarts of liquid blood. Right kidney in mass of infiltrated and bruised connective tissue, some of which had penetrated beneath the capsule, and a little was found free in the pelvis of the organ. Liver: transverse fracture behind the anterior border extending through the entire thickness of the organ, measuring six inches on the upper surface, and four and a half on the lower; on the inferior surface were two superficial cracks parallel to the main rupture.

CASE 10. Male, twenty-one years. Struck by train; lived seven and one-half hours. State of collapse. "External lesions wholly inadequate to explain the cause of death."

Autopsy, Dr. Draper. Bruises: both fore-arms, hands and right shin; over middle of ninth rib on the left. Fractures of left ankle, and ninth rib on the left. Pleura punctured under fracture of ninth rib. Abdominal cavity contained 24 ounces of liquid port-wine-colored blood. Pancreas: many superficial ruptures and lacerations. Liver: two or three quite deep rents on upper surface of right lobe, and two shorter ones on upper surface of left; some quite deep rents in the substance, and several large ragged ones in the lower surface. The kidneys lay in a mass of blood, but were themselves normal excepting pale.

CASE 11. Male, thirty-seven years. Caught between two cars. Died at once.

Autopsy, Dr. Draper. Bruises: across abdomen just below ribs, faint, indistinct, and four inches broad; on back between scapulae; at outer end of left eyebrow. Fractures: two of sternum; ribs (right 2, 3, 4, 5 and 6; left 2, 3, 4, 5, 6, 7, 8, 9 and 10). Spleen sound, but lay in a mass of blood-infiltrated tissue. Pancreas crushed off at one inch from its tail. Liver: between right and left lobes lacerated to the depth of three inches, and less severely on its upper surface. Kidneys: the left lay in a mass of blood-infiltrated and bruised tissue, and presented two moderate ruptures near its pelvis.

CASE 12. Male, sixty-five years. Knocked down and dragged by a horse-car. Lived fifty minutes.

Autopsy, Dr. Draper. Bruises: one in left lumbar region, scarcely perceptible and V-shaped; scalp-wound behind left ear, four and one-half inches long; no other external lesions. Fractures of ribs (right 4, 5, 6, 7, 8, 9, 10 and 11, and left 3, 4, 5, 6, 7, 8, 9, 10, 11 and 12). Pleural cavity contained about four ounces of blood. Lungs: in both lower lobes were a number of small punctures under the fractured ribs. Abdominal cavity contained about 80 ounces of blood. Spleen ruptured from outer surface inward nearly half-way through the organ; a smaller rent at extremity which was superficial. Kidneys: left had three ruptures, two of which were superficial, and one extending from outer surface through the organ into the pelvis.

CASE 13. Male, twenty-two years. Thrown down several times during a fight; "suddenly ceased resisting and seemed helpless." Lived nearly five days.

Autopsy, Dr. Draper. Unusually well developed and muscular man. Bruises: right eyelids, over outer end of right eyebrow, tip of chin, behind right ear, and over bridge of nose. In the right groin and left inguinal region the skin was bluish-green. Abdominal cavity contained seven ounces of thin sero-pus. Bladder lacerated as follows: externally two inches below and posterior to fundus, and to the left of the middle line, an elliptical opening two inches long and half an inch wide, leaving an opening three-sixteenths of an inch into the bladder; internally the mucous membrane was lacerated in crescentic form for a distance of two inches.

CASE 14. Female, twenty-eight years. Said to have fallen down stairs. Complained of retention and "great pain in her stomach"; was catheterized by a friend, who said that the urine was bloody. Retention and hematuria persisted; and she died five days later.

Autopsy, Dr. Draper. Bruises over both eyes, on back of right hand, outer side of right thigh, and crest of left ilium. Abdominal cavity; no peritonitis, cellular spaces between the bladder and navel were found dark grey, shreddy, and sloughing with a decidedly urinous odor. Urine had also dissected up the connective tissue behind the peritoneum as far as the posterior segment of the diaphragm, and downward into the deepest parts of the pelvis; this burrowing was entirely outside of the peritoneum. In the bladder wall posteriorly, to the right of the median line and extending in a vertical line from below upwards, was a rupture two inches long and involving the entire thickness of the vesical wall, crescentic and with its edges quite regular and symmetrical. The mucous membranes of the bladder presented disseminated patches, slightly elevated, red at the base and covered with a slaty gray membrane.

CASE 15. Female, forty years. History somewhat doubtful, but was probably assaulted and thrown down stairs by her husband. Lived about four days.

Autopsy, Dr. Draper. Bruises: there were 28 distinct bruises on face, arms, thighs, and in left iliac region—all on the anterior surface. Abdominal cavity contained 26 ounces of yellow, thin, fetid, purulent matter; general acute peritonitis; folds of intestine in hypogastric and pelvic regions were bruised in a circular direction around the gut. Intestines: two feet below the pylorus there was a rupture of the jejunum the size of a quarter-dollar, the edges reddened and everted, no induration at edges or

elsewhere. About the rupture on the inside of the gut the mucous membrane was reddened, and there was some ecchymoses in the mucous and muscular coats, in a transverse direction.

CASE 16. Male, forty years. Run over by heavy cart. Shock, followed by delirium tremens. Lived five days.

Autopsy, Dr. Gannett. Lacerated wound over elbow. Fractures of ribs (right, 2, 3, 4, 5, 6 and 7; left, 3, 4, 5 and 6). Lungs: recent fibrinous pleurisy, double pneumonia, effusion into both chests. Liver: three fractures, each about three centimetres long, and extending but a short distance (one millimetre) into liver substance. Abdominal cavity contained about 30 cubic centimetres of blood.

CASE 17. Male, fifty-three years. Delirious, and jumped from third-story window. Lived two days.

Autopsy, Dr. Gannett. Fractures: lower jaw, sternum and ribs (right, 3, 4, 5, 6, 7, 8 and 9; left, 4, 5, 6, 7 and 8); "old depressed fracture of skull," with small collection of blood between the dura and the pia over the occipital lobe. Pleura under the fractured ribs intact. Lungs: lower lobe of left atelectatic, and contained non-aerated fluid; lower lobe of right, dark-colored and quite firm from the presence of considerable effused blood. Abdominal cavity contained 50 cubic centimetres of fluid blood. Liver: transverse rent, about eight centimetres long, on right border of right lobe.

CASE 18. Male, forty years. Struck in the right side by a broken casting thrown from a centrifugal machine. Extreme shock. Lived about five hours.

Autopsy, Dr. Gannett. Ecchymosis along the lower border of ribs on the right side. Kidneys: rupture of right, with the extravasation of about 500 cubic centimetres of blood into the perinephritic connective tissue. Liver: multiple ruptures of right lobe, with the escape of 1,500 cubic centimetres of blood into the peritoneal cavity. Fractures of ribs (right, 5, 7, 8, 9 and 10).

CASE 19. Male, sixty-three years. Fell twenty feet, striking abdomen and chest on the rail of a vessel. Lived twenty hours.

Autopsy, Dr. Gannett. Visceral pleura showed numerous large ecchymoses. Peritoneal cavity contained 200 grammes of "pea-soup-like material." Intestine: rupture of jejunum large enough to admit the little finger; a foot lower down in ileum was a rent half-way across the bowel; still lower, another the size of a lead-pencil. Aorta: transverse rupture five centimetres long, with retro-peritoneal hemorrhage.

CASE 20. Male, sixty years. Caught under elevator. Extreme collapse. Lived eighteen hours. Catheterized three times, and no blood found either in gross or under the microscope.

Autopsy, Dr. Gannett. Fractures of ribs (right, 7, 8, 9, 10 and 11; left, 6, 7, 8, 9 and 10). Separation of eighth dorsal vertebra from its cartilage. Peritoneal cavity and retro-peritoneal tissue contained a large amount of blood. Kidneys: right at its anterior and upper extremity was extensively lacerated.

CASE 21. Male, twenty-three years. One week before entrance to the hospital fell from an empty wagon, the rear wheel passing over his loin and back.

On entrance the heart and lungs were normal except for a small area near the base of the left lung where there were a few "dry crackles." This was at the upper end of an area of dulness which extended from the pelvis up to about the seventh rib. Over this area of dulness there was some resistance and tenderness. General condition poor.

About one month after entrance an incision was made in the right lumbar region, and a large amount of fluid and clotted blood with a slight urinous odor was found in the tissues about the kidney, which was torn on its upper and inner surface. The urine before the operation contained a few blood-globules, which are still present at times but not constantly. This patient has gradually improved, but is still in the hospital, fifteen weeks after the injury, and ten after the operation.

CASE 22. Male, thirty-four years. One month before entrance to the hospital was struck in the epigastrium by a piece of wood thrown from a circular saw. During this month he was in bed most of the time on account of more or less persistent vomiting; the first vomitus was said to be bloody, after that it was not.

Upon entrance to the hospital a mass was felt midway between the ensiform cartilage and the umbilicus.

When operated upon, one week after entrance, this was found to be a cyst connected with the pancreas; "oozing from the walls of the cavity prevented any tear or lesion being actually seen."

Improvement was rather slow; and he left the hospital in good condition, but with a sinus still open and discharging a clear fluid.

Reports of Societies.

OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., SECRETARY.

REGULAR Meeting, Tuesday, March 16, 1897, the first Vice-President, DR. FRANCIS B. HARRINGTON, in the chair.

DR. CHARLES M. GREEN read a paper entitled

THE USE OF ETHER IN OBSTETRIC PRACTICE.¹

DR. A. WORCESTER read a paper entitled

THE SUPERIORITY OF CHLOROFORM AS AN ANESTHETIC IN MIDWIFERY PRACTICE.²

DR. E. P. DAVIS, of Philadelphia, read a paper entitled

CHLOROFORM IN OBSTETRICS.³

DR. NORTHROP, of New York: I was deceived as to the subject for discussion. I had not thought it was the question of chloroform or ether in obstetrics, but chloroform for general narcosis or for operations in general; and with that in view I began to communicate with some of my hospital surgical friends to find out, but at a late moment I learned that the field was narrowed to obstetrics. From New York I should say there was no ground for discussion as to which you should use, chloroform or ether. I do not know that I ever heard of anybody using ether except in prolonged surgical operations where the patient was to be put under deep narcosis. When I was a student from '76 to '78 we were taught that the pregnant woman and parturient woman was an entirely safe subject for the administration of chloroform; we were taught it was perfectly safe to administer chloroform to children; and never until this moment has it occurred to me to doubt that, and I have seen a little of the administration of chloroform both to parturient women and to children. It was always emphasized that we should use the Esmarch shield, that we should always use precaution, watching both the respiration and the pulse, but that we should not use it has not entered my mind until to-night. At the Foundling Hospital, where I have spent a good deal of my life, we have a Maternity Hospital, and we have for our interne staff men who have served in the Sloane Maternity, the Seventeenth Street Maternity, etc., so that there have been brought to the house all the different methods represented in these maternity services, and I

¹ See page 198 of the Journal.

² See page 196 of the Journal.

³ See page 193 of the Journal.

have had an opportunity to observe the practice by intelligent men from those places; and in every one of these institutions they use chloroform regularly at all births. Speaking from observation and experience, I think the Sloane Maternity conducts the service in the most exemplary manner of any. The men who come to us trained from the Sloane I think have been our best men. At the Sloane Maternity they have had 6,000 births. At each of those births as a routine they have given chloroform when the head was on the perineum. They claim the best results in saving perineæ, and I am convinced from what has been brought to me from men on the staff that they do not claim too much. In 6,000 cases they have probably given chloroform in every case with a few rare exceptions and those exceptions are, as I have stated, where they have been obliged to put the woman to the surgical relaxation, such as for version or prolonged high forceps. The other exceptions in which they give ether are in alcoholics who are brought in in parturition. In all valvular lesions of the heart, in alcoholics I think they make a distinction in favor of ether. The rule is chloroform; the exceptions are rare. They have about 600 births a year, and a man who had been there some time said he had not seen ether used at all; he was one of the assistants. At the Nursery and Child's Hospital a man who had been there thirteen months answered me over the telephone that they have about 170 to 180 births a year, and that practically no ether had been used in the thirteen months he had served there, that chloroform is given regularly in every case while the head is on the perineum. At the service of the New York Infant Asylum they have a birth a day. They have used with rare exceptions chloroform. Practically the same story is true of them all. I think I may say in taking all these institutions together, that they habitually use chloroform while the head is on the perineum, and in only rare exceptions is ether used, its use being limited to cases in which valvular lesions of the heart are present, to alcoholics and in case of prolonged operations.

I might go one step further as regards the use of chloroform in New York. In the Presbyterian Hospital I have the impression that in about one-third of the cases the question arises which shall be used, chloroform or ether. Chloroform is given in almost all abdominal operations, there being no positive contraindications. I remember Dr. Langer in a case of appendicitis saying he had no hesitancy in using chloroform. He uses chloroform, I think, equally with ether. Dr. Gerster said to me: "I think I use them about equally. In some very severe, prolonged operations, or where there is a cardiac complication, or in alcoholics, and for other reasons I give ether." I notice another feature in the surgeons at the Presbyterian Hospital. They frequently begin with chloroform, and if for any reason they think the patient would do better, they turn from chloroform to ether. They frequently begin the case expecting to do that, but in abdominal operations where there is no contraindication, they prefer chloroform. I do not think they have had anything to frighten them away from the practice. I think Dr. Lewis A. Sayre has boasted that he has not used anything but chloroform in his practice, at least with exceptions. It was a matter of interest and surprise to me that the matter stands as it does in Boston. Of course, locality prejudices do grow and grow strong; but I should say from my observa-

tions that in New York they use chloroform quite half as often as they do ether for short operations. I am interested in the discussion; it suggests a new experience in life.

Dr. WALLACE CLARK, of Utica, N. Y. This question has been very thoroughly put from the chloroform side. As to the question of chloroform and ether at the Lying-In Hospital, we have always used chloroform. I have never seen ether used there, and I think 90 per cent. of the operations in the Montreal General Hospital in my time were done under chloroform. I never during my life there administered ether. All operations, major or minor, were done under chloroform. Brought up in that way, I had no fear of chloroform. I see the feeling here is strongly against chloroform. That is a matter of local education. We were sure we had good chloroform to begin with, and that it was administered in small quantities, a small percentage of chloroform and a large percentage of air. Our mode of administering was to take a towel, make a cone with an opening at the top. Fifteen to thirty minims of chloroform were thrown on the inside and placed over the patient's face, at first a few inches from it, and gradually approximated. If you had a stronger percentage, the patient might object; but if it was held from the mouth a few moments, we had no difficulty with our patients. As I have seen ether administered, I have seen a good deal of struggling at first.

One of the prejudices towards chloroform in this country would be reasonably explained by an operation I once witnessed. I was asked to assist a surgeon at an operation. He determined to use chloroform, thinking there would be less vomiting. A friend of his who had been in the medical service during the war, — I don't think he had had any experience with chloroform, — prepared to administer the chloroform. He took the ether cone, put a sponge in it and threw in I should say two or three drachms of chloroform, clapped it over the patient's face and it was only a few seconds before he had spasm of the glottis, the man was choking, stopped breathing and here was a dangerous exhibition of chloroform. With an expression of contempt the man threw the cone from him. I offered to administer the chloroform if he would allow me, but they returned to ether.

In the obstetric use of chloroform, in doses of fifteen to thirty minims, it produces no disturbance. You ask the patient to breathe two or three breaths rapidly, and the relief comes quickly. The use of chloroform in the first stage is almost unnecessary. In the hyperæsthetic patient it is desirable, and perhaps more desirable, to use chloral by rectal enema. If you commence with chloroform in the first stage, it has a cumulative action; and in one-half to three-fourths of an hour you have the patient beyond the point where she retains her senses and assists in her labor. If commenced in the second stage, the action of chloroform in my hands has always been very satisfactory. I have never seen any trouble from chloroform administered surgically or obstetrically except in this one case; therefore, I do not feel that I have much to fear in the use of chloroform. In the use of chloroform in the operation of turning or using forceps I have never found it necessary to put them under complete narcosis. They hardly know anything about their delivery, even in the primary stage of chloroform. I myself have taken chloroform very often. If I have

a tooth to be extracted I sit down, throw myself back, take a towel sprinkled with chloroform, inhale it myself and instruct the dentist when to pull. You retain your senses very much better under the influence of it. But this question has been thoroughly discussed to-night, and the gentlemen who read the papers defended chloroform very satisfactorily and said all that need be said.

DR. J. G. BLAKE: I should be sorry if any gentleman carried away with him the fanciful picture the second reader gave us of the effects of ether. That is not the experience of most of us. If it was we should undoubtedly have sought for a more satisfactory anesthetic. We have used it in obstetrics here very extensively, and as far as I know with entire satisfaction. Of course, we have had but little experience with chloroform; but we have used ether, and we have not had very many of the symptoms set forth as the result of it. I want to enter a very decided protest against that description being accepted as the true one. I have not the least objection to anybody believing in chloroform, but I should like to ask these gentlemen if their use of it followed from an unsatisfactory experience with ether. We have been brought up on ether; at the same time I don't think we are prejudiced unduly against chloroform. In general surgery we have rested content with this remedy, which is safe as far as we know. We have been free from deaths in this community from the administration of ether in the different hospitals and in private practice. Particularly in obstetrics we have not seen any reason why we should discard an agent which perhaps is not as convenient in other ways as chloroform, but which has, to our minds and in our experience, the added element of safety. That is one of the reasons why we adhere to ether and do not feel justified in discarding it. It gives our patients all the relief that is called for from the administration of any anesthetic and at the same time imperils neither mother nor child. This is my feeling. I have not had a very extensive experience except in hospitals. When in the Massachusetts General Hospital thirty-seven years ago, I etherized a great many people. For the last thirty-two years at the City Hospital I have watched its use closely. In my own ward I have not the slightest trouble in bringing about primary anesthesia in forty to sixty seconds with ether. It depends a good deal upon the manner of giving it. It is not by drowning the patient, pouring it into the eyes and trachea, but by creating ether vapor and allowing the patient to breathe it from a large cone. When this is done and the patient's fears allayed, I have yet to see the case I cannot etherize pleasantly and successfully in a very short time.

DR. EDWARD REYNOLDS: I am extremely sorry that in a Society which has been for a number of years quite as much devoted to surgical as to obstetrical work this discussion should have been limited to purely obstetrical anesthesia. I am very sorry also that a large part of the discussion has been what seemed to me *ex parte* upon one side or the other. I myself am thoroughly satisfied with the use of ether in obstetrical work, and I fail to see the particular advantages of chloroform for the great majority of obstetrical cases. The arguments used for it fail to appeal to me. We can concede, I think, its safety. Ether unquestionably is dangerous to some few cases. I remember well one hospital patient upon whom I did a difficult craniotomy,

in the days when we did craniotomies, who died (to the best of my judgment) of ether. She was a short thick-set Jewess with chronic bronchitis. She died in three days with her lungs full, I think as a result of ether. I should not etherize such a patient again. I made up my mind then to the point that a patient with chronic bronchitis ought not to be etherized. Chloroform is less irritating to the bronchi.

As regards the influence of ether and chloroform upon the kidneys it seems to me as I follow the literature that the trend of opinion is not very pronounced as yet.

But the objections which have been made to the use of ether in labor, as I understand them, are, first, that it is unpleasant to the patient. That is not my experience. I use ether at one stage or another of practically every case of labor, and I have almost uniformly found that if properly given it is hardly disagreeable to the patient. I could count on the fingers of my two hands the number of times I have seen a patient object to taking ether in labor. They almost always object to its use for surgical purposes, but when it is given in labor at the beginning of each pain and the patient is allowed to take it as she wants to, she does not object, at least in my experience. I think that where it is carefully given in labor it rarely is followed by nausea of an amount to make any trouble or to be of any importance.

It is urged against ether in labor that it is too slow to control individual pains, and that if it is given in the interval it frequently annuls the pains altogether, and thus reduces us to the use of forceps. These difficulties are to a slight degree real, I think. I believe that the use of ether does sometimes lead us to use forceps, when if the woman had been allowed to struggle along with her pain we should not have had to use them. I, for one, am glad to have an opportunity of asserting that I believe that the greatest part of the strain upon women in labor is the pain of labor, that more women are injured in health by enduring the pain of labor to an undue extent than by almost any other cause. It always amuses me to hear men talk with bated breath of the possibility of coming to forceps. I think there is a good deal about this that is ridiculous. I do not hesitate to say that I use forceps, and propose to use forceps, freely; I use them in a large proportion of cases of labor; and I do not believe that they do harm when in the hands of any man who has obtained skill in their use and who is experienced in the conduct of labor. I believe I fear no more patients with forceps than without. I am quite disposed to believe, on the other hand, that in the obstetric operations which demand complete relaxation of the uterine muscle, chloroform should be the better drug. We all know that ether does not completely annul the action of the uterus. Any man who has seen many cases will, I think, have observed his not infrequent failure to completely control the contractions of the uterus by ether, even in cases in which the patient has gone off into extremely deep anesthesia immediately after the delivery of the child, that is, with the removal of the antidote to ether, pain. For some of these cases chloroform may be preferable for those who believe its obstetric use to be safe; which I myself think we must concede to the general experience of the profession.

DR. NORTHCUP: Regarding the effect of ether on the kidneys, I desire to speak of one case. A patient

had just recovered from an acute attack of nephritis, twenty-one days after the beginning of scarlet fever. Some days later I had occasion to cut down on the mastoid cells. I don't know where my wits were, but I gave the patient ether. The patient had had bloody urine before, and about the worst case I had ever seen. All symptoms had improved, and the color of the urine was right, but there followed such a beautiful illumination of the urine after the administration of the ether for a few days that I am not likely to forget it — suppression, convulsions, etc. I had occasion to go down to the same mastoid cells a few days later, and I gave chloroform, and there was no kidney reaction, although casts had been continuously numerous from the first. I thought it was a good control experiment.

DR. ENGELMANN: I must confess I had never given any serious thought to this subject. I have for many years used chloroform and seen it used, and have never heard any arguments to the contrary — we are speaking of chloroform in labor. In fact, I think the arguments this evening are rather favorable to the use of chloroform. I have always understood it has been conceded by the friends of ether that in obstetric cases there was no danger; and that is the one element, and I think the only one, which allows us to give the preference to ether. Barring that all the advantages are in favor of chloroform. It is more agreeable; can be used at the moment when it is wanted, and in small quantity and with rapid recovery; this, I think, has been admirably stated. The application of a few more drops brings the patient to the right state, with slight knowledge of what is going on; she does not feel the pains and comes to very quickly. As to ether, I think we may eliminate all danger in obstetric operations, unless it be in extreme cases of disease of the kidney or lungs, where chloroform is to be avoided; or in lesions of the vessels, where, I think, chloroform is somewhat risky, though I have given it in surgical operations with heart disease, with an assistant extremely careful — and that, by the way, is essential to the successful giving, and I have no doubt that those who thoroughly understand the use of ether will see more satisfactory results in the lying-in room than we who do not understand. The use of chloroform, naturally, must be understood. I have always used in labor, for the relief of the ordinary pains, a few drops on the handkerchief. You can gauge that, and it is all consumed, and the patient has only so much for that pain. That is the one advantage we claim for chloroform, that its action is rapid. As we see the approach of the pain a few drops are given to carry the patient over that pain; and where suggestion is desirable, a mixture of chloroform and cologne may be used. I should say, too, if any here have used chloroform, they may have had some unpleasant experience, because I have found it difficult to obtain a satisfactory article unless I purchased a pound. We don't know what the condition of that is until we test it. It is deteriorated by exposure to light, by shaking; I have always presumed it is by frequent opening of the bottle. I have always secured six-ounce bottles; and Squibbs makes them, so that you always have a fresh bottle as it comes from the still. I have always felt, seeing the excellent results from chloroform and no injurious results, that those who use chloroform in labor use it because they become accustomed to its administration in surgery, had seen it used in the hospitals, and so it was the one agent to which they were habituated; and then I pre-

sume the power of popular influence has much to do with it. But the small quantity of chloroform used in labor, and the rapidity of its action at the proper moment should speak in its favor, even to those who use ether on account of the much greater quantity and its permanent or lasting effects. It may be safe, but it is not as pleasant and as satisfactory a remedy if you will give the chloroform a fair trial.

DR. GEORGE HAVEN: I have used chloroform in the hospital in Vienna, in Winckel's clinic, the four months I was connected with it, and I never saw a bad result from chloroform. It was very much easier to give, and the patient got relief from pain much quicker than from ether. We used it not only in obstetric practice, but in gynecological patients. I never saw on the continent ether used but once, and then the patient nearly died from the effects of ether badly given. It was given in a very confined cone, and death almost resulted from it. They threw the ether cone down and began with chloroform. Since coming home I have never used chloroform but once or twice, and have devoted myself entirely to ether in obstetric practice. I think chloroform has advantages in so far that less chloroform is used and the patient is rendered comfortable in a very much shorter time than with ether. I don't know what the community of Boston would say if chloroform was given and death should occur. I think the man would be very seriously blamed and would get a very unenviable reputation. That it is used in New York and in the South and West with immunity I think is a very striking fact. I think ether is perfectly satisfactory; and chloroform I think a little easier to the patient and a little easier for the person giving the anesthetic.

DR. A. D. SINCLAIR: I was brought up to the use of chloroform under the man who introduced it in medicine; and for a period of two years I gave chloroform to one, two, three or four every day, not knowing or fearing any danger from it. It was given freely according to the directions given by Professor Simpson, which were a few drops on a towel held a few inches from the face and gradually approximating the face. I never saw but once anything that approached danger, and that was where the patient did not recover from the effects of the anesthetic for nearly twenty-four hours; nor did there a death occur to my knowledge in the city of Edinburgh, either in any of the hospitals or in private practice during a period of two years, with the exception of one which took place at the Royal Infirmary in a patient who had heart disease. We have other things parallel to it. We give medicines a while and there is wonderful success, and then everything goes the other way. By and by we began to hear of deaths from chloroform. Every few days you would hear of deaths in the various hospitals, particularly the English hospitals.

I cannot help thinking, as Dr. Clark says, that there has been some looseness in the administration of chloroform. Not everybody does everything as he ought. There is a coarse way of doing things. I have seen men taking charge of an obstetric case, and who had taken charge of many cases, work as though they had elbows instead of fingers. One who has given ether is not fitted, unless he has especial training, to give chloroform. I think that locality has much to do with one's practice. I had no fear from the use of chloroform, and had seen ether given and given it frequently when I was house-officer at the Massachu-

setts Hospital. With both of these drugs I was familiar, and would have continued the use of chloroform in Boston on my return, but I felt that there was greater safety in ether from the fact that just about that time we began to hear of these frequent deaths. I heard a gentleman say the other day, that when he was a student in Dublin he was told that a death from chloroform took place daily at some place or other in Great Britain. I do not think that is true. Chloroform is more dangerous than ether in general administration, but in obstetric cases I don't think it is.

DR. J. P. REYNOLDS: I want to put a question to the last speaker, because I think he has a very interesting fact to mention as to safety in the prolonged use of chloroform. Dr. Sinclair will bear testimony, I believe, to its continued employment for a very great number of hours.

DR. SINCLAIR: Professor Simpson believed that chloroform was of all others the anesthetic in children's cases. In one case of convulsions in a child chloroform was administered for fourteen days; I don't know how much. The child was kept constantly under its influence a fortnight.

DR. J. P. REYNOLDS: I heard the same thing from the late President of this Society, who said that he had known it to be given for six days. I was anxious to bring that fact out. I have listened with the greatest interest to what has been said to-night, and one of the speakers expressed precisely my own feeling when he said it was greatly to be regretted that this question should be approached in a partisan spirit. I have no such feeling. I think we recognize in Boston that both chloroform and ether have proved themselves to be, at least in obstetrics, entirely innocent remedies. I for one am very glad to hear all that has been said to-night in favor of the use of chloroform, but I contest most strongly, as other gentlemen have, the account of the evils of ether. During the greater part of my life in a practice largely obstetrical I have used ether in almost all cases of labor. There is no such thing as continuous nausea under its administration. Vomiting may occur when it is first given, but not afterward. How often, indeed, when in severe surgical operations vomiting has appeared to be coming on has an operator called out: "The patient is going to vomit. Crowd the ether."

I have heard with the greatest interest what was said about the use of ether in the hospitals. I have a strong feeling that a lying-in hospital will never do its full duty to women in labor until it can provide the means for giving an anesthetic, be that ether or chloroform. Last fall I had occasion to ask the opinion of gentlemen in different parts of the country in regard to the employment of anesthesia in private practice for normal labor. I did not preserve the replies, but I read them carefully, and the result was an almost universal testimony that it was not freely used, that it was but little given in normal labor for the relief of pain. I share most deeply the conviction which one gentleman has expressed to-night that the risks of childbirth bear a close relation to the endurance of pain. We may talk of parturition as merely a physiological process like respiration, defecation or micturition, but it is for the dangerous cases of labor that obstetrics exist, precisely as when an incoming ship is in peril that men need the pilot. Whatever the so-called stage of labor the moment pain begins to tell upon the courage and strength of the woman the time

has come to relieve her distress; and, moreover, if in the latter part of the process danger is to develop in any direction, the attendant has in this way done his best service by guarding the strength of the patient and her power of vital resistance.

Something has been said of the method of giving ether in labor. I have learned to think that ether in obstetrics is best given to the exclusion of air. My own plan takes no concern for the access of atmospheric air. I cover the mouth and nose, and do not care to leave any aperture at the end of the cone.

As to hemorrhage, I bear like testimony with that given so impressively in this city by the late Dr. Fordyce Barker. He did not believe that anesthesia predisposed to hemorrhage; he should rather say that the cases in which he had seen post-partum hemorrhage occur were those in which for some reason or other no anesthetic had been given. He was speaking of chloroform. My own experience with ether is precisely that.

DR. ENGELMANN: If I recollect aright, among the many interesting facts given us by Dr. Reynolds at the time of the ether celebration, he spoke of the neglect of the use of the anesthetic, that is, of ether in labor, because it might prolong the labor a half-hour or so. It struck me at the time, because I should say with chloroform we expect to shorten the time of labor; and then I think he mentioned there (he did here) that the use of anesthesia, that is, ether, in labor was diminishing. Throughout the West and South it has been my experience that the use of anesthesia is increasing, that is, chloroform. I want to know whether he means that in the region where ether is given that less is used in labor than formerly.

DR. J. P. REYNOLDS: The address to which the gentleman refers was prepared without means of consulting authorities or taking advice of professional friends. It was not until the night before I delivered it that I had the opportunity of reading once more the statements of Dr. Barker that I had quoted only from memory. As spoken, the address made it clear that Dr. Barker had in mind chloroform. My assertion that anesthesia was little used in normal labor even with private patients was based on replies from gentlemen in parts of the country where the anesthetic employed is almost exclusively chloroform. In several instances chloroform was mentioned as the agent.

DR. J. B. BLAKE: I have a few notes on the after-effects of ether in entirely surgical cases. The reason for giving ether at the City Hospital in surgical cases is because we are taught, and have known from large statistics in this country and in England and those quoted by Gurlt in Germany, that the deaths after anesthesia were six for chloroform to one for ether. Those were taken, as I say, throughout the Continent and correspond very closely to the results found in England and the results in America. That fact, however, does not do away with the equally well-known fact that following ether are certain undesirable effects which exist and have been to a certain extent underestimated. In the last three months I have observed the cases that came to operation on the Third Surgical Service at the Boston City Hospital, and questioned the patients as to the after-effects. The result is as follows: In 158 cases of various sorts of operations there was more or less vomiting in 53, or 33 per cent. The frequency of vomiting varied considerably with the experience of the person who gave ether. One

of the surgical dressers, who was in his sixth month of service, had a percentage of about 5 per cent. instead of 33 per cent., showing that with the greater experience of the anesthetizer there was a less amount of vomiting. Patients were all given ether breakfasts. The vomiting was, as a rule, moderate in amount. In three or four cases it was excessive, in one-fourth very slight.

Another symptom noted was nausea distinct from vomiting. In 94 cases questioned for this symptom nausea was present in 38. Nausea did not necessarily coincide with the vomiting, but came in certain cases without vomiting, in certain cases with the vomiting, and in certain cases was not mentioned, although vomiting was severe.

Frontal headache existed in 36 out of the 94 cases, and lasted, as a rule, two to four hours. In only two cases did it continue during the night of the operation.

The final point investigated was cough; and in 18 cases the patient spoke of having some slight cough the day of the operation. In three cases the cough lasted twenty-four to seventy-two hours, and in two was accompanied with a certain number of moist râles in the chest.

In 20 only of the 94 cases was there an absence of all symptoms. I do not know of any similar recent compilation of statistics in regard to chloroform, and I should be very glad to hear of any.

DR. J. P. REYNOLDS: I ought perhaps to say that lately, in looking over my own records, I was surprised to find here and there a note that I had withheld or abandoned ether in a given case because it seemed that the patient's pains did better without it.

DR. C. B. PORTER: I had no thought of saying anything when I came here, but I feel as though I ought to say something, having had experience so many years in the administration of ether. I was brought up by one of the strictest adherents of ether, Dr. Bigelow, who up to the very last years of his life tried to investigate every case of death said to have been caused by ether; and I have heard him make the statement that in all cases there was some other definite good cause than the ether. I myself have had now something like thirty years' experience in giving ether, and I have never had a death from that cause. I remember but one death that has occurred on the operating-table in my hands, and that was a case of long-standing strangulated hernia brought in almost *in extremis*. I think Dr. Sinclair said that those who are accustomed to give ether ought not to give chloroform unless they had especial training; and I should say those accustomed to give chloroform do not, unless they have had especial training, understand how to give ether. Ether, in the majority of cases, can be given very expeditiously, very safely, without vomiting, if the person who gives it understands its administration. It is the one thing I have felt that our young men do not understand unless they have had the personal hospital experience, and even then they do not comprehend all that is essential; and for that reason for the last two years special instruction has been given to the students in the matter of administering ether.

I have been very much interested in hearing what has been said by the gentlemen who have been accustomed to give chloroform, and have been also very much pleased to think that it has been given in their hands with so much safety. In this block within the last two weeks I promised to give chloroform because

my patient disliked ether; and I took the trouble to read up the subject of the rules of the administration the night before. I gave the chloroform myself, because I said if anything happened to the patient I wished to take the blame and not have it on my assistant's hands. I gave a whole ounce on the handkerchief, and spent an hour and a quarter trying to get him under the effect and then gave it up and pushed the ether. It was because I did not understand the administration of chloroform, because I etherized him in a very few minutes. I can but say, as I have followed the commissions on the other side of the water, it seems to me there has been a constantly increasing tendency to use ether and give up chloroform.

DR. H. L. BURRELL: There are four classes of cases in which for the last five years I have been in the habit of using chloroform. I think possibly a half-dozen times during the course of a winter I use chloroform. I do not mean in all of these cases that I use chloroform every time, but I always consider whether chloroform or ether is best for the individual patient. The classes of cases are: first, head operations; second, where there is any obstruction to respiration, and especially in tracheotomies; third, where I know there is a chronic bronchitis; and, fourth, where there is a strangulated hernia.

DR. RICHARDSON: I have been very much interested in the discussion of this subject. As everybody knows, we use ether almost exclusively, and have no fault to find with it. I believe we are coming to use chloroform a little more in general anesthesia, especially in cases in which anesthesia must be used, when there is a bronchitis or any lung trouble and when the kidneys are much affected, but even in such cases I think the dangers of ether are very slight. I do not recall a case in which there has been a death from ether. Cases have died during anesthesia, but they have been cases which would die probably just the same without anesthesia, as I recall them, particularly cases of strangulated hernias, which seem to be particularly liable to sudden death. With the use of ether we feel perfectly safe, as Dr. Blake has said; and we do not know how to give chloroform, as Dr. Porter has said. I remember seeing one of the strongest advocates of chloroform use it to wire a jaw; and he used chloroform until he got tired of it, and then used ether to produce anesthesia. That was the first time I saw chloroform used. I don't know anything about the use of chloroform or ether in obstetrics.

I think the strongest argument in favor of ether as a general anesthetic is the fact that we feel sure the patient will come out of his anesthetic, and we shall not have that terrible misfortune of sudden death in the course of anesthesia for a trivial operation. If we are doing an operation which carries a large mortality with it, that is one thing; but if we feel that every time we produce anesthesia for the opening of a feloo or an operation for fistula, that the patient may die on the table, I for one should not have any peace of mind whatever in approaching these trivial operations. I dare say we do not know how to give chloroform, but I have always understood that the dangers of chloroform were without premonition.

DR. J. B. BLAKE: I don't want our guests to leave Boston with the idea that preferring ether was a Boston fad at all. Our apprehension of chloroform is founded on the statistics of death from its use, and works on surgery furnish a sufficient justification for.

our not going away from a safe though perhaps not as convenient an anesthetic as chloroform. Recent writers give the situation as one death for every 3,000 administrations. The percentage seems small, but we do not have even a sixth of that with ether; and so when we have this safe agent we feel disinclined to run the risk of one death in 3,000. I am not referring to childbirth.

DR. F. B. HARRINGTON: I had always used ether for primary anesthesia until two years ago, when I was induced to try chloroform. I found that patients liked it better, that it was more convenient, and that it was speedier. I don't think there is much nausea after primary anesthesia from either anesthetic when properly used.

About six months ago I gave chloroform in order to explore a sinus, and I nearly lost the patient, although she had taken only a few inhalations. I have not used chloroform since, and do not intend to use it, except for those cases in which it is universally recognized as superior to ether. The question is one of safety. I feel that the disadvantages of ether are more than offset by its greater safety. The deaths from anesthetics are not numerous; but one cannot forget that they are six from chloroform to one from ether.

DR. A. WORCESTER: I am quite sure our guests will go away with a clear understanding of the reason why chloroform is not used in Boston; for if chloroform fails to produce anesthesia in the hands of our very able surgeons, no wonder it is not popular. I am sorry the discussion has wandered from the lines laid down. Our real purpose was to discuss the relative merits of ether and chloroform in labor; and not the slightest intimation has been offered that it ever did any harm in its obstetrical use. I think nobody who has used both has failed to admit that its use is very much more agreeable to the patient, which ought to count for something. The facts that it is more pleasant, that the patient comes out more easily and can be relieved of pain and at the same time not made wholly unconscious, are advantages that with any obstetrician certainly are very weighty. I am sorry that my description of the use of ether in midwifery practice is taken too seriously. I did not mean that every time ether is used such would be the result; but I am just as sure that such untoward results and the necessity of using forceps are sometimes due to the use of ether. I believe in ether. I should rather favor it if I were to be put under an anesthetic for fourteen consecutive days. I believe that ether is better in prolonged operations. But I also firmly believe that chloroform is better in normal labor in relieving the woman in the second stage and in the stage of delivery. I believe it is not only perfectly safe but that it ought to be given. There are a few gentlemen who use ether in almost every case; but the practice in this community is not to give an anesthetic in normal labor. We are behind the times. Women ought to have an anesthetic, and the reason anesthesia is withheld is because their physicians insist that they can be more safely delivered without an anesthetic. The reason physicians so insist is because they know only the disadvantages of ether and are not acquainted with the advantages of chloroform; and it is a pity and a shame in a centre so advanced as we hope Boston is in other respects that generation after generation of physicians should be sent out of Boston who do not know how to use chloroform.

DR. CHARLES M. GREEN: I confess that I am surprised at the picture drawn by Dr. Worcester of a case of labor conducted with ether. I have always used ether in the manner described in my opening remarks; and I have never witnessed such a deplorable spectacle. On the contrary, my patients have expressed their gratitude for ether, and have seldom shown any disagreeable effects, such as bronchial irritation and vomiting. I acknowledge that Boston is a small, conservative and provincial town; but I think I may claim that we have learned how to use ether. Moreover, we like to arrive safely at our destination, even although we take a slower steamer, with smaller state-rooms and poorer table perhaps. The advocates of chloroform anesthesia have not yet explained away the facts shown by Gurlt's statistics, that the fatalities from chloroform are from four to ten times as many as from ether: until they do this, I shall myself prefer to "hold fast that which is good."

DR. PORTER: When in Vienna and watching Billroth operate, he gave ether, as he said, and the patient was supposed to be etherized. Billroth commenced to cut, whereupon the patient sat up on the bed and delivered one of Cicero's orations, and was pushed back on the table and more ether given. Even as great a man as Billroth did not understand the administration of ether.

DR. WALLACE CLARK: In reference to the point that chloroform does not nauseate: in deep narcosis we nearly always have nausea; in primary anesthesia we do not have it. I very seldom use chloroform without finding, as they are coming out or going in, that they do vomit.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

NINETEENTH ANNUAL CONGRESS, HELD AT
WASHINGTON, D. C., MAY 4-6, 1897.

(Continued from No. 8, p. 186.)

DISCUSSION ON ATROPHIC RHINITIS.

DR. CASSELBERRY spoke of its Nature and Symptoms. He said that there are in reality two forms of this disease. One occurs in children and the other in old people. Another division is into fetid and non-fetid. No one causative theory answers for all cases. The atrophy might be due to one cause and the fetor to another. Still another division of the cases was into the simple dry, and into the ozenatous varieties. All stages of atrophy could be seen leading up to the degeneration of the mucous glands and the formation of crusts. The non-fetid variety is more common in elderly people, while ozena occurs more frequently in early life. In some cases the two types seem to blend.

One cause of the disease may be some disturbance of the local peripheral sensory nerves. The nostrils become less sensitive and the pharyngeal reflexes more sluggish. The nasal bones and cartilages become affected, and the nose assumes a similarity to the saddle-back shape seen in syphilis. The nasal tip is tilted up so that the anterior nares look forward rather than downward. Another theory as to causation is that of a primary central trophic neurosis. Congenital malformations may lead to atrophic rhinitis from poor ventilation of the nasal chambers and stagnation of secretion. Syphilis, tuberculosis, alcohol

and gout all seem to come into play in some cases. In both types the atrophy varies in degree and distribution. Hypertrophy need not have exhausted itself before atrophy begins. The middle turbinate may be hypertrophied, while at the same time the inferior is atrophied. Other theories were those of Gruenwald, who ascribed the affection to sinus disease; and of Bosworth, who referred it to a preceding purulent rhinitis. The germ theory had also been invoked by several investigators.

The symptoms of the condition were familiar. They did not need repetition here. In addition to the strictly intra-nasal features, pain across the nose was sometimes present. Impaired hearing or alteration of the voice were frequently the first symptoms to call the attention of the patient to his catarrhal state.

DR. J. N. MACKENZIE spoke of Pathological Changes. Our task, he said, was to determine the nature and order of the lesions which occur in this disease. It must be remembered that we are dealing with an important physiological organ as well as with a mucous membrane. Our present haze of opinion is due first, to our loose use of the term "atrophy," and, second, to our failure to discriminate between the different forms of atrophy and the causes producing them. There may be a simple atrophy or the atrophy of degeneration. The best term to use is "sclerosis." This implies an atrophy of the specific nasal tissues, a hypertrophy of the connective-tissue elements, cell infiltration, granulation tissue, the obliteration of old and the formation of new blood-vessels. This sclerosis may result from blood infection, as in syphilis and tuberculosis, or from intoxication, especially that of alcohol. He did not believe that purulent catarrh was a cause of atrophic rhinitis. Such a pathological sequence had no known parallel in disease processes. The task of the future is to determine the causes of this sclerosis. The process can be atrophic from the beginning, but the speaker regarded this as improbable.

DR. C. C. RICE, of New York, spoke of Treatment. He would divide it into local and constitutional. The latter included hygiene in its broadest sense. He had seen much good result from a change of occupation; from the factory, for instance, to the farm, and from an indoor life to one out of doors. He would especially advise against the use of cigarettes, which he regarded as pernicious.

As to local measures, they could be included under the headings of stimulation, antiseptics as far as possible, and absolute cleanliness. As stimulating agents, a host of various drugs had been employed. Electricity had also been employed for this purpose, both the galvanic and the faradic currents having their respective advocates. More recently cataphoresis had been used, the copper salts serving as the medicinal agent. All the drugs could be used on tampons, in bougies or by inhalation. Massage would benefit some cases. All destructive agents should be avoided.

He would strongly advocate the use of the oily preparations, which were lubricants, and served as vehicles for other substances. They should be applied by friction, and the process might be described as that of polishing the nose. In young children with profuse watery discharge, powders might be used. The cleansing fluids should be used with the ordinary douche cup which was plenty large enough to carry the amount of liquid necessary.

DR. WRIGHT called attention to the fact that atrophic rhinitis was far more common in women than in men, and that it was confined practically to the child-bearing period. He thought that this fact must have some bearing on etiology.

DR. J. H. HARTMAN, of Baltimore, had for some years used electricity, and was still greatly impressed with its usefulness. The only trouble was that the method was tiresome for both the patient and the physician.

DR. JAMES E. LOGAN, of Kansas City, was inclined to regard sinus disease as, in some cases, at least, the cause of the atrophic rhinitis. He thought that the middle turbinate acted as a sort of drip-stone or drain for the sinus. In a group of seven cases he had curetted the sinus, with most satisfactory results upon the condition of the atrophic nasal mucosa.

THIRD DAY.—THURSDAY.

SIMULATED SARCOMA OF THE TONSIL.

Paper by DR. D. BRYSON DELAVAN, of New York.

The patient was a man of forty-three years. His family history was negative as to tumors, and there was no evidence of syphilitic disease. For two months he had had a swelling of the left tonsil, and with a breaking down in the centre, leaving a cavity with overhanging edges. The remainder of the organ was indurated, and the cervical glands below the tonsil were enlarged. There was pain on deglutition and palpation. A bit of the tonsil was removed and submitted to several pathologists for their opinion. All were disposed to regard it as a sarcoma; but one of them, Dr. Hodepuy, was inclined to dissent from this view. The sections showed chronic hyperplasia of the tonsillar tissue and an arrangement of the endothelial cells suggesting sarcoma. Under the iodide the glandular enlargement cleared up; and as the tonsil did not increase in size, it was decided to remove it by the cold snare. This was successfully done, and the patient made a good recovery.

A NEW METHOD OF PERMANENT RELIEF FOR CERTAIN ENLARGEMENTS OF THE TURBinate BODIES.

Dr. Delavan also presented a brief communication with this title. The object was to permanently reduce the size of the congested bodies. He advocates the making, under cocaine anesthesia, of a submucous incision by means of a small, fine knife—almost a needle in fact. It should be swept around under the mucosa, and withdrawn through the channel of entrance, care being taken not to enlarge the latter. It was better to repeat the operation than to overdo it. There was but little pain and but slight bleeding. Cocaine should be kept in contact with the turbinate for several hours after incision. Hemorrhage should be allowed to stop of its own accord. The operation had four distinct advantages: it was easily done, had a freedom from bad effects, preserved the mucosa, and possessed a practical adaptation to the desired end. He would lay no claim to originality in the matter, though he had never seen the procedure described.

DR. WRIGHT thought that the operation acted by breaking up the coats of the blood-vessels, causing a clot formation in the cavernous tissues. The procedure was a logical one, as it was just what we tried to do in certain cases of aneurism.

DR. CASSELBERRY saw many cases of posterior engorgement in which this plan would not answer.

He was willing to admit, however, that the reduction of the anterior portion would often lead to a reduction of the posterior without further interference. He also alluded to the method of submucous linear cauterization recently advocated by Dr. Pierce of Chicago.

SUBGLOTTIC TUMOR REMOVED BY TRACHEOTOMY AND CURETTING.

Paper by DR. JOHN W. FARLOW, of Boston.

Patient was a woman of 37, who for four years suffered from difficulty in breathing. Three years ago she came under the care of a physician in St. Louis, who was able to discern the tumor. Tracheotomy was done, and it was found that there was a mass about one and one-half inches long by three-eighths of an inch in width situated on the posterior wall of the trachea and bulging into the esophagus. It was sessile, of a brownish color, soft consistency, and of the thickness of a lead-pencil. Removal was deemed unadvisable at that time, owing to the danger of forming an intractable tracheo-esophageal fistula.

After the tracheotomy the patient felt considerable relief, but continued to have great trouble at times with her breathing. She came under Dr. Farlow's care in January of the present year. There was only a very narrow passage for the entrance of the tidal air. The voice was not hoarse and the vocal cords moved freely. The appearance was that of three masses, two on the right side and one on the left. The tumor was regarded as non-malignant and a diagnosis made of enchondroma.

A low tracheotomy was done by Dr. Richardson in February, and the trachea was cut down from above. About one and one-half inches below the cricoid was found a single mass with a lobed appearance which was removed with the curette. Bleeding was not at all troublesome. The skin was sutured, but the rings of the air-tube were not. The tracheotomy-tube was removed in five days. Patient made a good recovery. Microscopical examination revealed fibroma.

PAPILLARY EDEMATOUS NASAL POLYPI AND THEIR RELATIONS TO ADENOMATA.

Paper by DR. JONATHAN WRIGHT, of Brooklyn.

The writer described several cases reported in literature and several seen by himself. In some of them tumors shown to be true adenomata had occurred in connection with polyps; and the paper went to show that in the nasal cavities all gradations of structure could be met with, from an ordinary edematous polyp to a true adenoma.

A CASE OF ADENO-CARCINOMA OF THE NOSE.

Paper by DR. F. E. HOPKINS, of Springfield, Mass.

His patient was a hale and hearty man of eighty-three years, with a negative family history as regarded tumors, but with a tubercular taint. For twelve years he suffered from nasal obstruction and a watery discharge. There was no pain or bleeding. Six years ago an operation for removal was undertaken, but given up on account of severe hemorrhage. Later, forceps were applied and some pieces (which might have been polyps) removed from the nostrils. In April of the present year he came under the writer's care. No operative interference had been undertaken for three years. He had at this time occasional epistaxis, offensive odor from the nares, and a constant sanious mucous discharge. One eye was displaced outwards

and the septum nasi had been forced over to the right side, the mass presenting in the left naris. The growth was removed with the cold-wire snare without incident, except that the bleeding was profuse. Examination of the mass showed it to be made up very largely of cylindrical cells arranged in some places in tubules and in others in acini. In still other places there were irregular cell masses. In general there was a tendency to a concentric arrangement. The connective tissue was scanty in amount. Diagnosis, primary adenocarcinoma.

A FURTHER CONTRIBUTION TO THE STUDY OF LARYNGEAL PHTHISIS.

Paper by DR. T. MORRIS MURRAY, of Washington.

This was a review of the various methods of treatment proposed since a previous paper read in 1893. He would lay special stress on the value of creosote, which he regarded as a *sine qua non* in tubercular laryngitis. He also stated that he had had excellent results with one of the digestive preparations called "enzymol." He had used it to digest off necrotic tissue, and had been much pleased with its action.

PRIMARY LUPUS OF THE LARYNX.

Paper by DR. EMIL MAYER, of New York.

The clinical histories of two cases were given in detail, and the statement made that 14 other cases are recorded in literature. It is now established beyond any question that lupus may originate as a primary deposit in a mucous membrane without any external manifestation, and that it is dependent upon the tubercle bacillus.

A differential diagnosis must be made between tuberculosis, syphilis, cancer, leprosy and lupus. Primary lupus is without symptoms for a long time. There may be no fever at all. The voice eventually becomes husky, and dyspnea may supervene. The glands may or may not be affected. Clinically, the primary disease resembles the secondary. The pathological process comprises four stages: paleness of the mucosa, edema, ulceration and cicatrization. A given case may present all forms at the same time.

The malady runs a chronic course, without fever. Cure may be spontaneous, and the lesion after reappears in the scar. Death ensues from complications, but is rare from glottic edema. Conclusions are

- (1) Primary lupus of the larynx does exist.
- (2) It is painless, and may be unnoticed for years.
- (3) Tubercle bacilli are present in scanty numbers, but difficult to find.
- (4) The disease resembles in appearance syphilis rather than tuberculosis.
- (5) The absence of adhesion bands is characteristic of lupus, while they are always found in late syphilis.
- (6) The prognosis as to life is fairly good.

DR. SWAIN recalled one case, that of a girl who had old scar tissue in the larynx, of the existence of which she was totally unaware. Under tuberculin injections it took on a pinkish color, though there was no adverse reaction and the injections were without any therapeutic benefit.

DR. WRIGHT thought that it was almost impossible to draw a hard and fast line between lupus and tuberculosis. Cases which looked like lupus would frequently clear up under the iodide, thus proving themselves to be syphilitic. One case of his own, supposed to be lupus, was relieved by this remedy. A few ba-

cilli were found, but later general tuberculosis of the lungs and larynx set in. It was customary to speak of such cases as mixed infection, but personally he had but little faith in this theory.

FOUR CASES OF SARCOMA OF THE NOSE.

A paper on this subject was read by J. E. H. NICHOLS, M.D., of New York. The clinical histories of the cases were given in detail.

DR. JOHN O. ROE, of Rochester, presented

AN INSTRUMENT FOR THE DILATATION OF STENOSIS OF THE TRACHEA.

During the Executive Sessions of the Congress, the following gentlemen were elected to Active Fellowship:

J. Payson Clark, M.D., Boston; Thesis, "Nasal Polypi."

J. Edwin Rhodes, M.D., Chicago; Thesis, "Atrophic Rhinitis."

Richard Frothingham, M.D., New York City; Thesis, "Benign Retro-pharyngeal Tumors, with Report of Cases."

James A. Logan, M.D., Kansas City, Missouri; Thesis, "Laryngitis Rheumatica, with a Report of Cases."

To corresponding fellowship: H. Luc, M.D., Paris, France.

The following papers were read by title:

J. C. MULHALL, M.D., St. Louis, "The General Health and the Upper Respiratory Organs."

H. L. WAGNER, M.D., San Francisco, "Surgical Treatment in Acute Inflammation of the Tonsillar and Peritonsillar Regions."

J. H. HARTMAN, M.D., Baltimore, "A Case of Angioma of the Tonsil, with Recurrence of the Same Three Years after Removal."

T. H. HARDIE, M.D., Chicago, "The Advantage of Bromide of Ethyl in Adenoid Operations."

The annual election of officers for the coming year resulted as follows: President, Thomas R. French, M.D., of Brooklyn; First Vice-President, Alex. W. McCoy, M.D., of Philadelphia; Second Vice-President, Herbert S. Birkett, M.D., of Montreal; Secretary and Treasurer, Henry L. Swain, M.D., of New Haven; Librarian, J. H. Bryan, M.D., of Washington.

It was voted to hold the next meeting in Brooklyn, the date to be selected by the Council.

Recent Literature.

A Short Practice of Midwifery. Embodying the Treatment Adopted in the Rotunda Hospital, Dublin. By HENRY JELLETT, B.A., M.D., B.Ch., B.A.O. (Dublin Univ.), F.R.C.P.L., L.M., Assistant Master, Rotunda Hospital. With a Preface by W. J. SMYLY, M.D., F.R.C.P.L., Late Master of the Rotunda Hospital. With 45 Illustrations, and an Appendix containing the statistics of the hospital for the last seven years. Philadelphia: P. Blakiston, Son & Co. 1897.

This little book of some 300 small pages has been written, the author states, with the object of giving a concise and practical description of the treatment, which has been, during seven years, so successfully

carried out in the Rotunda Hospital under the master-ship of Dr. W. J. Smyly, and which is still followed by his successor, Dr. R. D. Purefoy. The work, therefore, while giving at the same time a brief sketch of the whole subject of obstetrics, is of great value and interest to the practitioner.

In the first chapter, on Asepsis, the author disapproves heartily of routine ante- or post-partum douching. Both of these are, however, indicated in certain cases, and should then be given by the physician himself with great care. He prefers the creolin douche, corrosive sublimate being almost useless for the purpose of douching. In the management of the third stage he waits until the uterus has itself expelled the placenta, and he then expresses the placenta from the vagina.

The chapters on Instrumental Deliveries are excellent, brief rules for indications and method being given with great clearness.

The chapter on Accidental Hemorrhage and Placenta Previa is of great interest. Concealed accidental hemorrhage with intact ovum he believes can only take place with a diseased uterus which dilates before the blood pressure. The only treatment is *accouchement forcé* or Pond's operation. In placenta previa, *accouchement forcé* he believes to be bad, as the patient is in danger of dying of shock, although the chances for the child are improved. The best treatment he considers to be that of Braxton Hicks, consisting in bipolar version, rupturing the membranes, drawing down a foot, and leaving the rest of the delivery to nature.

He naturally turns with interest to the chapter on Eclampsia. To arrest the fits he prefers morphine, given at first in a half-grain dose subcutaneously, followed by one quarter grain every two hours. Chloroform and chloral depress the heart seriously and favor heart failure. He recommends not to induce labor; but if it occurs spontaneously, to shorten its duration as much as possible, without employing undue violence. Do not adopt *accouchement forcé*. Venesection may be useful in the case of a strong plethoric patient.

Lectures on Appendicitis and Notes on Other Subjects.

By ROBERT T. MORRIS, A.M., M.D. Fellow of the New York Academy of Medicine, American Association of Obstetricians and Gynecologists, American Medical Association, etc. Second Edition, Revised and Enlarged. With illustrations by HENRY MACDONALD, M.D. New York: G. P. Putnam's Sons. 1897.

This brochure is divided into five chapters, the first four of which deal with appendicitis. The last chapter contains notes upon the personal views and the results of experimentation of the author; for example, "The Prevention of Secondary Peritoneal Adhesions by Means of an Aristol Film," "Another Method for Palpation of the Kidney," "Is Evolution Trying to do Away with the Clitoris?" "Two Cases of Conservative Surgery of the Arm," and "Subsequent Notes on Appendicitis."

Dr. Morris's views as to appendicitis are well known. He has an attractive style in writing. He puts his subject clearly, forcibly and with sufficient detail to make it intelligible and of practical use. He is a close observer, and carefully records what he sees. This makes his lectures extremely interesting. The volume is excellent as a piece of book-making.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, AUGUST 26, 1897.

ETHER AND CHLOROFORM.

UPON the comparative safety and advantages of ether and chloroform as anesthetics the accumulation of statistics has gone on for many years, with the result that on statistical evidence, ether, as is well known, has been shown to be actually the safer anesthetic, causing one death in about 15,000 administrations, while chloroform causes one death in about 3,000 administrations.

The reason for this is not difficult to find, owing to the well-known fact, established by physiological experiment and clinical evidence, that ether is a cardiac stimulant, and chloroform a cardiac depressant.

The dangers which are to be combated during the administration of ether are connected with hypersecretion of the respiratory mucous membranes, with obstruction of the air passages by falling back of the tongue, with tonic contraction of the masseters, etc., dangers which result in asphyxia, and which can be directly and successfully met by measures directed to their treatment, and capable of being carried out by any anesthetist of average skill.

The danger, *par excellence*, of chloroform anesthesia, is, however, sudden syncope from cardiac paralysis, due to chloroform intoxication, an accident which is as likely to occur in strong as in weak subjects, happens more frequently at the beginning than at the end of anesthetization, presents conditions of the greatest difficulty for treatment and frequently results in death. In the face of these conditions, although the superiority and greater convenience of chloroform in certain cases in cerebral surgery, operations on the respiratory passages, etc., may give it preference in these operations, its adoption as a routine anesthetic ought to be condemned.

Leonard Hill, M.B., Lecturer on Physiology at the London Hospital, in his address on "The Causation of Chloroform Syncope," delivered before the London Society of Anesthetists on February 18, 1897, and

published in the *British Medical Journal* for April 17, 1897, makes some remarks upon this subject, which coming from England, where, as is well known, chloroform for many years completely displaced ether, and even now is the anesthetic most frequently used, are of especial interest.

"Chloroform" says Hill "is a drug used by the young anesthetist with the utmost hardiness; and until he has the misfortune in his practice to meet with a death caused by it, he derides the danger of the drug, and asserts that its safety merely depends on the care and skill of the administrator. After losing his patient he falls to descanting upon the unavoidable dangers of the drug, dangers which he is now the first to maintain cannot be met by any degree of skill in administration. In a certain institution in Great Britain, in the course of a recent year, there were out of some three or four thousand administrations no fewer than twelve fatalities. This is no exceptional case. The deaths from chloroform are not recorded in the medical journals, for these reflect upon the reputation of the administrator and the institution in which they occur."

The chief interest of Hill's address, however, is its presentation of experimental evidence on the causation of chloroform syncope, the result of careful experimentation upon animals by himself, in conjunction with Harold Barnard, M.S., F.R.C.S., and C. Wall, B.A., of the London Hospital.

The paper is directed, as Hill states, "towards the establishment of the true pathological causes of chloroform syncope, and the controversion of one of the most pernicious and dangerous doctrines ever put before the medical profession. This doctrine, so long received by many with credence, is that chloroform kills by paralyzing the respiratory centre. Supported by the wealth of the Hyderabad Government, furthered by the prejudiced enthusiasm of Surgeon-Lieutenant-Colonel Lawrie, this statement, upheld by a series of experiments, many so careless in execution that they could not for one moment be accepted by a trained physiologist—this doctrine that the paralysis of the respiratory centre causes chloroform syncope, has been industriously spread abroad, and instilled into the minds of the whole medical world."

After the introduction follows a denial of the too common teaching of clinicians that the results of animal experimentation are inapplicable to man, a statement which is simply a confession that the clinician knows too little of experimental physiology to elucidate the problem before him. Out of the enormous mass of literature bearing upon the question of chloroform and ether, but few papers can be found based on experimental investigation.

By Snow before the use of the graphic method, and by the Glasgow Committee and others after its introduction, it was established that chloroform produces a fall of arterial pressure. While admitting this fact as incontrovertible, the Hyderabad Commission also found, as Hill claims, by careless and inadequately planned experiments that the respiratory centre became para-

lyzed before the heart. This statement Hill denies, and quotes the results attained by MacWilliam, who found, in several animals, sudden failure of the heart during primary anesthetization, while the respiration remained unaffected. This failure was found to be due to paralytic dilatation of the heart.

Gaskell and Shore, and Hare and Thornton, found that the injection of chloroform into the jugular veins produced cardiac *followed*, and not preceded by respiratory failure, a fact which the Hyderabad Commission failed to find, owing to the fact, according to Hill, that pure instead of diluted chloroform was injected, that the vein was tied above the point of injection, and that a needle was used as an indicator of cardiac action. An insufficient acquaintance with physiological methods has characterized the entire work of the Hyderabad Commission. Gaskell and Shore found by careful and ingenious experimental methods that the heart is rapidly paralyzed by chloroform, and the respiratory centre is paralyzed, while the vasomotor centre is excited to increased action.

Into the experimental work of Hill and Barnard, which introduces most interesting applications of change of position upon the circulation, with or without anesthesia, and which deals with the effect of chloroform upon cardiac inhibition by electrical excitation of the vagus, with the phenomena of fatal syncope at an early stage, which Hill found to be as frequent in dogs as in men (in one year out of 41 recorded deaths from chloroform syncope, 39 occurred during the primary stage of anesthesia, and before the surgeon had touched his patient), with syncope during prolonged anesthesia, and with the treatment of syncope, we have not space to go. The original account will well repay a careful reading. The conclusions of the author, which follow, give an adequate idea of the results of his carefully conducted experiments, and serve to confirm the position of those surgeons who object to the use of chloroform as a routine anesthetic. Hill's conclusions are as follows:

1. Chloroform produces a primary failure of the circulatory mechanism and a secondary failure of the respiratory centre. The respiratory centre fails to act not only because it is damaged by the drug, but because of the anemia of the spinal bulb produced by the fall of arterial tension. This is proved by the fact that the action of the respiratory centre can be renewed by raising the arterial tension. The depth of anesthesia depends, as does the paralysis of the respiratory centre, on the primary fall of the arterial tension.

2. Chloroform, more than any other known agent, rapidly abolishes the vascular mechanisms which compensate for the hydrostatic effect of gravity.

3. Chloroform abolishes these mechanisms by paralyzing the splanchnic vasomotor tone, and by weakening the action of the respiratory pump. When these mechanisms are totally abolished, the circulation is impossible if the subject be in the feet-down position.

4. Chloroform also produces paralytic dilatation of the heart. It acts directly like amyl nitrite on the musculature of the whole vascular system.

5. There are two forms of chloroform syncope: (a) During primary anesthetization. The patient struggles, holds his breath, raises the intra-thoracic pressure, congests his venous system, lowers his arterial tension, and finally takes deep inspirations and surcharges his lungs with chloroform. In the first stage the left heart becomes impoverished; in the second

stage it is suddenly filled with blood. This is drawn from the lungs, and is full of chloroform. The chloroform passes into the coronary arteries, and the heart is thrown into paralytic dilatation. Respiration and the pulse either cease simultaneously, or the pulse before respiration. (b) During prolonged anesthetization this arises from gradually giving chloroform to too great an extent. The arterial pressure falls lower and lower, and, secondarily, the respiration ceases because of the anemia of the spinal bulb. The heart is not in this case paralyzed by chloroform, because the drug is taken in gradually by the shallow respirations, and distributed slowly by the feeble circulation.

6. Artificial respiration and the assumption of the horizontal position, if applied in time, will always resuscitate a patient from the second form of syncope.

7. Artificial respiration, established with the patient in the horizontal posture, is also the treatment indicated in the first form of syncope; the heart should be rhythmically compressed by squeezing the thorax. If this does not quickly renew the pulse, the patient should be put into the vertical feet-down posture. The dilated right heart is thereby completely and easily emptied of blood. Artificial respiration is maintained during this manoeuvre, and the patient is brought once more into the horizontal posture. By rhythmic compression of the chest an efficient circulation is maintained through the coronary arteries; by first emptying and then filling the heart a fresh supply of blood is brought into that organ. If this does not prove successful on the first trial it can be repeated.

8. Inversion, that is, placing the subject in the feet-up position or compression of the abdomen will increase the paralytic dilatation of the heart. In this kind of syncope both these forms of treatment are worse than useless.

9. In the condition of shock or emotional fear the compensatory mechanism for the effect of gravity is almost abolished, and chloroform may easily be the last straw to completely paralyze the circulation.

10. Vagus inhibition of the heart is of no importance as an agent in the production of chloroform syncope.

11. Ether is in every respect a far safer anesthetic than chloroform. According to Ringer's experiments on the heart, ether is fifty times less dangerous than chloroform.

12. With the practical conclusion of the Hyderabad Commission that the chloroform inhaler should be removed during the struggling of the patient or when the respiration is of irregular depth, I am in absolute agreement, but I consider their interpretation of their own experiments and tracings concerning the origin of chloroform syncope to be mistaken.

Not only the work of all physiologists, but also the tracings of the Commission, when rightly interpreted, prove that paralysis of the circulatory mechanism, and not of the respiratory centre, is to be dreaded by the anesthetist.

MEDICAL NOTES.

NO PLAGUE IN HONG KONG.—Though bubonic plague has been prevalent in several parts of South China, and within a very short distance from the Colony, Hong Kong has thus far escaped during the present year, only four cases, three of which were in one house, having been reported up to the end of June.

SURGEON-GENERAL STERNBERG IN MOSCOW.—Surgeon-General George M. Sternberg, U. S. A., is now in Europe to attend the meeting of the International Medical Congress in Moscow. He will present two papers to the Congress, one entitled "The Bacillus Icteroides of Sanarelli (Bacillus X, Sternberg)," the other, "The Radical cure of Inguinal Hernia in the United States Army."

"MEDICINE, PAST AND PRESENT, IN RUSSIA," A CORRECTION.—The medical press seems to be occasionally liable to a class of errors which are perhaps

more frequently seen in the daily papers. The *Lancet*, in a recent article, says: "We regret that, through an unfortunate inadvertency, in the article on the Moscow Congress in our issue of July 31st, the portrait of the late Dr. Botkin (Fig. 3, p. 274) was described as that of Prof. N. V. Sklifosowski. Similarly, in our supplement published last week, the portrait of Professor Sklifosowski (Fig. 13, p. 373) was labelled Prof. S. P. Botkin." And it expresses a hope that the error has not been the cause of any annoyance to the esteemed joint president of the organizing committee of the Congress.

A PROVING OF THE BACILLUS ICTEROIDES.—A physician in Uruguay, Dr. Antonio Quesada, has offered to subject himself to inoculation with the bacillus icteroides in order to prove the correctness of Sanarelli's assumption that it is the pathogenic agent of yellow fever. All attempts to turn Dr. Quesada from his purpose by pointing out its dangers have been unavailing, so that with every precaution the experiment will be conducted in the presence of a few selected physicians, who will carefully note the progress of the case. Dr. Quesada is a robust man, forty-two years of age, who was formerly a surgeon in the Spanish army, serving in the Philippines and in Cuba. He made a deep study of yellow fever while in Cuba, but asserts that he has never had the disease. He professes absolute confidence that the experiment will prove the value of Sanarelli's researches. — *Medical Record*.

THE DEATH-RATE OF HAVANA.—In striking contrast to the progressively decreasing mortality in New York since the middle of July is the excessively high and constantly increasing death-rate in the city of Havana. The reports of Dr. Brunner, the United States Sanitary Inspector of Havana, show the following almost incredible figures: Annual death-rate per thousand of the population for the week ending July 15th, 61.10; for the week ending July 22d, 68.61; for the week ending July 29th, 73.84; for the week ending August 5th, 79.56; and for the week ending August 12th, 82.42.

SANITARY CONDITIONS IN HAVANA.—The following is an extract from the report of Sanitary Inspector W. F. Brunner of the United States Marine Hospital Service, dated Havana, August 13, 1897. "The heat for the past ten days has been intense, the trade winds have been light, and there has been an absence of the daily rainfall for about one week. It has been almost impossible to remain any time exposed to the direct rays of the sun without serious results, hence the harbor work has been very trying. In spite of all the conditions existing, which are supposed to favor the spread of yellow fever, it would appear from the mortality table in this report that this disease is decreasing. This appearance is not real. As stated in a previous report, the deaths from yellow fever are being absorbed by those credited to other diseases. The military hospitals are filled with patients, and it

is a well-known fact that patients brought to the hospitals in and around this city suffering from some other cause will invariably develop yellow fever soon after admission if there is not a history of a previous attack."

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, August 25, 1897, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 29, scarlet fever 18, measles 10, typhoid fever 28.

NEW YORK.

CONTINUED LOW MORTALITY.—During the week ending August 14th there were reported in the city 769 deaths, a mortality representing an annual death-rate which is announced by the Health Department to be the lowest for the week of the corresponding period of the year in a record of twenty-five years. This record is beaten in the report of the week ending August 21st, when there were only 750 deaths, representing an annual death-rate of 19.58 per thousand of the population, which is estimated at 1,998,686. One of the most gratifying points in the report is the fact that, while 335 of the total number of deaths were in children under five years of age, there were only 118 deaths from diarrheal diseases in persons of all ages, which would seem to be an almost unprecedented showing at this season. Another gratifying feature is that there was not a single death reported from sunstroke. The deaths from contagious diseases have also reached a very low mark; there having been only 5 from measles, 2 from scarlet fever, and 16 from diphtheria.

IMPROVEMENT IN THE MILK-SUPPLY.—The annual report of President Wilson of the Health Board, relating to the milk product and its consumption in the city, shows that there has been a marked improvement in the quality of the milk-supply, especially in that of milk sold by the glass in the vicinity of the public schools, and that the percentage of adulterations has been far less than formerly. While in the year 1895 there were 408 arrests for selling adulterated milk, in 1896 there were but 220 such arrests.

SURVIVAL OF STAB WOUND OF THE HEART FOR NINE DAYS.—An interesting fact was developed at an autopsy made by Drs. McFadden and Conrad at the Hackensack Hospital on August 21st, in the case of a patient who had died the previous night from the effects of a stab wound inflicted August 11th. The autopsy showed that the point of the knife had entered some distance into the cardiac tissue; yet the man had survived for more than nine days.

DEATH AT THE AGE OF ONE HUNDRED AND ONE.—Mrs. Catharine Penelena died on August 21st at Nyack, New York, at the age of one hundred and one years and five months. She was born in England, and removed to this country after the death of her husband, about forty years ago. She had always enjoyed re-

markedly good health, and was ill for but two days before her death, which was apparently due to her advanced age.

Miscellaneous.

THE HAHNEMANN HOSPITAL COLLEGE AND THE UNIVERSITY OF CALIFORNIA.

A PETITION has been presented to the Regents of the University of California by the Hahnemann Hospital College for admission to affiliation with the University of California, and a counter-petition by the regular Faculty of the Medical Department of the University.

At a meeting of the Regents of the University held August 10th, both petitions were heard, but the final vote will not be taken till the next meeting, to be held September 9th. We append the two petitions:

We, the undersigned, Directors and Stockholders of the Hahnemann Hospital College of San Francisco, having been appointed a special committee by the Board of Directors of the said institution to present to your honorable body a petition praying for the affiliation of the Hahnemann Hospital College of San Francisco with the University of California, thereby forming a Homeopathic Department of the University, do hereby ask that such prayer may be granted.

The Hahnemann Hospital College of San Francisco was incorporated in 1881, and threw open its doors to students in June, 1884, since which time it has given a regular course of lectures each year, in all branches of medicine and surgery. There have been graduated from said institution 125 students, and there are at present 27 students in the various classes.

The College has always demanded a high standard of education from its graduates. It required three full years of study in the College from its beginning, and was, with the Medical Department of the University of California, the first to demand a full four years' course of study in the College, as a compulsory requirement for graduation. The College, though not endowed, is wholly free from debt. There are in the State of California, in actual practice to-day, about 2,300 licensed physicians of all schools, of which number, by actual count, 465 are of the Homeopathic school, about one-fifth of the whole number.

As the patrons of Homeopathy are among the well-to-do class of citizens and not so much among the masses as the patrons of other schools, it is undoubtedly a fact that such patrons pay at least one-third of the taxes of the State.

Because we believe it to be for the best interests of the Hahnemann Hospital College of San Francisco, for Homeopathy on the Pacific Coast, for the large number of citizens and tax-payers of this State who do now and who may in the future employ Homeopathic physicians that the said College should be under the protection of the State University, and also because we believe it to be for the best interests of the University of California, as a great university, that there be a Homeopathic Department connected with it, we do therefore pray that the Hahnemann Hospital College of San Francisco may become affiliated with the University of California.

A petition has been placed before your honorable body by the Homeopathic School of Medicine of this city praying that they be made an affiliated College of the University of California, which would therefore constitute them a teaching body of the University of California. There is, however, already a Medical Department of the University of California, which has always discharged its duties faithfully and unselfishly, working zealously for the honor of the University and for the advancement of medical knowl-

edge. The present Medical Department feels that it would be an unjust criticism of their work if another faculty were appointed, and tantamount to an assertion by the Regents that the work of the present Faculty was incomplete from a University standpoint.

If such an opinion be held by the Regents, then it is only fair that they should first apprise the present Faculty of its deficiencies so that an attempt may be made, if found necessary, to rectify them.

But the present Faculty of Medicine does not believe that the Regents have any intention to make such a criticism of its present Faculty of Medicine. They believe that the Regents in lending an ear to the petition of the Homeopathic School of Medicine are simply wishful to find if it might be for the greater advancement of the University to take in a school which asserts itself to be possessed of a more enlightened and successful mode of treatment than any other so-called school or collection of individuals now practising medicine.

The following facts would seem, however, to indicate that their boast of having a superior mode of treatment or a more advanced knowledge of medicine than the regular school of medicine is not well founded.

Homeopathy began in 1810 with the publication by Hahnemann of his "*Organon der rationellen Heilkunde*." From then till now, a period of eighty-seven years, all scientific advance has found a ready ear and quick appreciation in all the civilized countries.

Let us now examine carefully what respect and appreciation the homeopaths have been able to win either from the scientific world or from the general public.

They are not recognized either in the army, navy or civil service of any government in the world, including our own.

They are recognized by no institution of learning in any foreign country, and by only two institutions of learning in our own country, namely, Ann Arbor and the University of Iowa. Johns Hopkins University, for example, that particularly prides itself on its work of investigation, has not a single homeopath on its medical faculty.

There are very few homeopaths in Germany, the birth-place of the founder, and no university there teaches homeopathy, and the verdict of the scientific world has been endorsed by the general public in so far that all steamships, all railroads, and all life insurance companies choose almost invariably the medical services of the regular profession.

During all the eighty-seven years that the homeopaths have been in existence we cannot recall a single instance of a scientific discovery in the field of medicine by one of their number, nor the fostering of scientific thought in one of their schools.

The discovery of the sleep-producing effect of ether and chloroform were made by regular medical men, working in regular medical schools.

Lister, the originator of antiseptic surgery, from which the whole vast progress of modern surgery dates, is a regular physician and surgeon.

Koch, the discoverer of the cause of consumption and of cholera is a regular medical practitioner, working in a regular school.

Pasteur, a chemist, worked under the auspices of a regular medical school.

The discovery of the germ causing typhoid fever, and in fact the whole system of modern sanitary medicine and quarantine measures, have developed under the influence of the regular school of medicine.

The serum treatment for diphtheria by Behring was instituted by a regular working in the University of Berlin, a regular medical school.

The great medical events of our own city have been carried out by members of the regular profession. The curing of an aneurism of the abdominal aorta by John F. Morse, the perfecting of the crushing operation for stone of the bladder by Chismore, and the finding of a rare form of skin disease close to a parasite called a psorosperm by Rixford, have all been done by members of the regular profession.

Both Professor Le Conte and President Jordan, two of the most distinguished leaders of thought in the natural

sciences in this country, are graduates from regular medical colleges, and although not engaged in the practice of medicine, yet serve to show that an education in a regular medical college does not dull a man's intellect or render him illiberal.

This list of discoveries, investigators and educators proves, if it proves anything, that the regular medical profession is not inimical to progress.

It is therefore not likely, if homeopathy were in the line of progress, that it would meet with opposition from such an enlightened body of men as compose the regular medical school.

And furthermore it is to be said that not one of the propositions put forward by the Homeopathic Medical School has advanced out of the realm of theory into that of actually realized fact; and this after a trial of eighty-seven years, in an age of scientific progress.

[If Homeopaths, as such, are to have representation in a State University, then why not other medical and other sectarians, as such, because they pay taxes? Why not Eclectics, Christian Scientists and Osteopaths?—ED.]

PLEASURE WITHOUT OTHER SENSATIONS.

THE following, quoted in the *New York Medical Journal*, is of much interest, both to the physician and psychologist:

E. W. Scripture, Ph.D. (Leipsic), of Yale University, has sent us the following: "While exploring the sensations of various parts of the body about a year ago, I chanced to notice a phenomenon of which I find no mention in the various physiologies and psychologies. I submit the brief statement in the hope of learning if any one has previously made a similar observation, or if the fact which I have repeatedly observed can be confirmed by physicians who have the possibility of testing large numbers of patients. The observation may be summed up as follows: Whereas the surface of the glans penis is moderately sensitive to the pointed end of a toothpick and responds strongly to the point of a pin, the mucous membrane around the orifice of the urethra is absolutely lacking in sensations of touch in either case, although strong pressure with the point of a pin will cause pain. There is, however, another sensation aroused by the application of any object to this mucous membrane—namely, that of pleasure—which increases directly with the degree of erection. The confirmation of this observation would establish the hitherto unrecognized fact of the separate existence of pleasure as an independent sensation, a fact of considerable importance in the psychology of feeling."

"CARDING" THE SCIATIC NERVE.

THE operation of "carding" or "harrowing" the sciatic nerve for very obstinate sciatica was first performed about a year ago by Dr. Delagénière of Mans in a case in which he presumed that the cause of the pain was a varicose condition of the veins surrounding the nerve. The intention was to excise those veins after the method recommended by Quénu; but when the nerve was exposed, instead of the varix he expected, he found only a number of small serpiginous vessels running along it, causing the surface to present a furrowed appearance. It was obviously impossible to ligature and resect these, so he contented himself with easing or carding the fibres with a blunt forceps throughout the whole exposed portion of the nerve in the hope of destroying the vessels existing in its deeper

parts and of thus being able to put an end to the stasis in the venous twigs. The result was that the patient was cured.

This encouraged another French surgeon, Dr. Gérard-Marchand, to attempt a similar process which he denominates *hersage* or "harrowing" in sciatica where there was no reason to suppose that a varicose condition existed. The first case was that of a woman, age thirty-seven years, who was unable to sleep or to stand upright, characteristic scoliosis being present.

There were no signs of varicose veins or of hysteria. The second was that of a man, age forty-five years, with a very old-standing sciatica, no treatment having been of any avail. Here also there were no varicose veins. The operation, which was similar in the two cases, was performed under chloroform, and consisted in exposing the nerve and teasing apart its fibres for a distance of two centimetres by means of a grooved director. The appearances were normal, there being no discoloration and no dilatation of the vessels. After the *hersage* the nerve was flattened out to twice its ordinary breadth. A drainage-tube was inserted and the wound sutured and dressed with iodoform and absorbent cotton wool. For several days the patient complained of pain in the nerve and of numbness in the limb. The pain, however, gradually passed off and sensation returned, complete recovery resulting in both cases. From experiments on animals Dr. Gérard-Marchand has been led to conclude that *hersage* of the sciatic nerve produces temporary loss of sensation in the nerve, while the motor power is not interfered with. He suggests that probably this operation may be found of value in the case of other neuralgias which have resisted all ordinary treatment.

The above account, for which we are indebted to the *Lancet*, calls to mind the procedure of stretching the sciatic nerve, which several years ago was given a rather general trial in the treatment of obstinate cases of sciatic neuralgia. It is to be hoped that it may more satisfactorily stand the test of time, though the similarity of the two procedures points somewhat against its efficacy.

STATISTICS OF ANESTHESIA.

The Vienna Surgical Society has published in the *Journal für Zahnheilkunde* further statistical returns on the subject of anesthetics, which have been collected by Dr. Gurlt. The administrations reported are 58,769 in number, including 27,000 of chloroform, with 29 deaths; about 19,000 of ether, with 3 deaths; 5,000 of Billroth's mixture (morphia chloroform and alcohol), without a death; 996 of bromide of ethyl, without a death; and 5,890 of chloroform and ether, without a death. During the last two years 32 deaths have been reported, being 1 death in 1,836 administrations. Altogether, 327,953 administrations, with 134 deaths, have been reported since the year 1891, being a proportion of 1 in 2,444.

Arranged according to the resulting mortality, the various anesthetics appear as follows: Pental, 1 death in 213 administrations; chloroform, 1 in 2,039; Billroth's mixture, 1 in 3,897; ether, 1 in 5,019; bromide of ethyl, 1 in 5,228; chloroform and ether, 1 in 7,594. The mortality from chloroform has increased from the year 1891 to the year 1897, the figures being as follows: In 1891, 1 death in 2,700 ad-

Addresses.

BRITISH MEDICINE IN GREATER BRITAIN.¹

BY WILLIAM OSLER, M.D., F.R.C.P.,

Professor of Medicine, Johns Hopkins University, Baltimore.

To trace successfully the evolution of any one of the learned professions would require the hand of a master—of one who, like Darwin combined the capacity for patient observation with philosophic vision. In the case of medicine the difficulties are enormously increased by the extraordinary development which belongs to the history of the present century. The rate of progress has been too rapid for us to appreciate, and we stand bewildered and, as it were, in a state of intellectual giddiness, when we attempt to obtain a broad, comprehensive view of the subject. In a safer "middle flight" I propose to dwell on certain of the factors which have moulded the profession in English-speaking lands beyond the narrow seas—of British medicine in Greater Britain. Even for this lesser task (though my affiliations are wide and my sympathies deep) I recognize the limitations of my fitness, and am not unaware that in my ignorance I shall overlook much which might have rendered less sketchy a sketch necessarily imperfect.

Evolution advances by such slow and imperceptible degrees that to those who are part of it the finger of time scarcely seems to move. Even the great epochs are seldom apparent to the participants. During the last century neither the colonists nor the mother country appreciated the thrilling interest of the long-fought duel for the possession of this continent. The acts and scenes of the drama, to them detached, isolated and independent, now glide like dissolving views into each other, and in the vitascope of history we can see the true sequence of events. That we can meet here to-day, Britons on British soil, in a French province, is one of the far-off results of that struggle. This was but a prelude to the other great event of the eighteenth century: the revolt of the colonies and the founding of a second great English-speaking nation—in the words of Bishop Berkeley's prophecy, "Time's noblest offspring."

Surely a unique spectacle that a century later descendants of the actors of these two great dramas should meet in an English city in New France! Here, the American may forget Yorktown in Louisburg, the Englishman Bunker Hill in Quebec, and the Frenchman both Louisburg and Quebec in Chateaugay; while we Canadians, English and French, in a forgiving spirit, overlooking your unseemly quarrels, are only too happy to welcome you to our country—this land on which and for which you have so often fought.

Once, and only once, before in the history of the world could such a gathering as this have taken place. Divided through the Greeks were, a Hellenic sentiment of extraordinary strength united them in certain assemblies and festivals. No great flight of imagination is required to picture a notable representation of our profession in the fifth century B. C. meeting in such a colonial town as Agrigentum, under the presidency of Empedocles. Delegates from the mother cities, brilliant predecessors of Hippocrates of the stamp of Damocedes and Herodicus, delegates from the sister colonies of Syracuse and other Sicilian towns,

from neighboring Italy, from far distant Massilia, and from still more distant Panticapæum and Istria. And in such an assemblage there would have been men capable of discussing problems of life and mind more brilliantly than in many subsequent periods, in proportion as the pre-Hippocratic philosophers in things medical had thought more deeply than many of those who came after them.

We English are the modern Greeks, and we alone have colonized as they did, as free peoples. There have been other great colonial empires, Phœnician, Roman, Spanish, Dutch and French, but in civil liberty and intellectual freedom Magna Græcia and Greater Britain stand alone. The parallel so often drawn between them is of particular interest with reference to the similarity between the Greek settlements in Sicily and the English plantations on the Atlantic coast. Indeed, Freeman says: "I can never think of America without something suggesting Sicily, or of Sicily without something suggesting America." I wish to use the parallel only to emphasize two points, one of difference and one of resemblance. The Greek colonist took Greece with him. Hellas had no geographical bounds, "Massilia and Olbia were cities of Hellas in as full sense as Athens or Sparta." While the emigrant Britons changed their sky, not their character, in crossing the great sea, yet the home-stayers had never the same feeling toward the plantations as the Greeks had toward the colonial cities of Magna Græcia. If, as has been shrewdly surmised, Professor Seely was Herodotus reincarnate, how grieved the spirit of the father of history must have been to say of Englishmen, "nor have we even now ceased to think of ourselves as simply a race inhabiting an island off the northern coast of the continent of Europe." The assumption of gracious superiority which, unless carefully cloaked, smacks just a little of our national arrogance, is apt to jar on sensitive colonial nerves. With the expansion of the Empire, and the supplanting of a national by an imperial spirit this will become impossible. That this sentiment never prevailed in Hellas, as it did later in the Roman Empire, was due largely to the fact that in literature, in science and in art, the colonial cities of Greece early overshadowed the mother cities. It may be because the settlements of Greater Britain were things of slower growth that it took several generations and several bitter trials to teach a lesson the Greeks never had to learn.

The Greek spirit was the leaven of the Old World, the workings of which no nationality could resist; thrice it saved western civilization, for it had the magic power of leading captivity captive and making even captive conquerors the missionaries of her culture. What modern medicine owes to it will appear later. "The love of science, the love of art, the love of freedom—vitally correlated to each other, and brought into organic union," were the essential attributes of the Greek genius (Butcher). While we cannot claim for the Anglo-Saxon race all of these distinctions it has in a higher degree that one which in practical life is the most valuable, and which has been the most precious gift of the race to the world—the love of freedom,

"Of freedom in her regal seat
Of England."

It would carry me too far afield to discuss the differences between the native Briton and his children scattered so widely up and down the earth. In Canada,

¹ The Address in Medicine at the British Medical Association, Montreal, September 1, 1897.

South Africa, Australia and New Zealand types of the Anglo-Saxon race are developing which will differ as much from each other, and from the English, as the American does to-day from the original stock; but amid these differences can everywhere be seen those race-qualities which have made us what we are—"courage, national integrity, steady good sense, and energy in work." At a future meeting of the Association, perhaps in Australia, a professional Sir Charles Dilke with a firm grasp of the subject may deal with the medical problems of Greater Britain in a manner worthy of the address in medicine. My task, as I mentioned at the outset, is much less ambitious.

Could some one with full knowledge patiently analyse the characteristics of British medicine he would find certain national traits, sufficiently distinct for recognition. Three centuries cannot accomplish very much (and that period has only just passed since the revival of medicine in England), but the local conditions of isolation, which have been singularly favorable to the development of special peculiarities in the national character, have not been without effect in the medical profession. I cannot do more than touch upon a few features, which may be useful as indicating the sources of influence upon Great Britain in the past, and which may perhaps be suggestive as to lines of progress in the future.

Above the fireplace in Sir Henry Acland's study are three panelled portraits of Linacre, Sydenham and Harvey; the scroll upon them reads *Litteræ, Praxis, Scientia*. To this great triumvirate, as to the fountain-heads, we may trace the streams of inspiration which have made British medicine what it is to-day.

Linacre, the type of the literary physician, must ever hold a unique place in the annals of our profession. To him was due in great measure the revival of Greek thought in the 16th century in England, and in the last Harveyian oration Dr. Payne has pointed out his importance as a forerunner of Harvey. He made Greek methods available; through him the art of Hippocrates and the science of Galen became once more the subject of careful, first-hand study. Linacre, as Dr. Payne remarks, "was possessed from his youth till his death by the enthusiasm of learning. He was an idealist devoted to objects which the world thought of little use." Painstaking, accurate, critical, hypercritical perhaps, he remains to-day the chief literary representative of British medicine. Neither in Britain nor in Greater Britain have we maintained the place in the world of letters created for us by Linacre's noble start. It is true that in no generation since has the profession lacked a man who might stand unabashed in the temple at Delos; but judged by the fruits of learning, scholars of his type have been more common in France and Germany. Nor is it to our credit that so little provision is made for the encouragement of these studies. For years the reputation of Great Britain in this matter was sustained almost alone by the great Dec-side scholar, the surgeon of Bauborchy, Francis Adams,—the interpreter of Hippocrates to English students. In this century he and Greenhill have well maintained the traditions of Linacre. Their work, and that of a few of our contemporaries, among whom Ogle must be specially mentioned, has kept us in touch with the ancients. But by the neglect of the study of the humanities, which has been far too general, the profession loses a very precious quality.

While in critical scholarship and in accurate historical studies, British medicine must take a second place, the influence of Linacre exerted through the Royal College of Physicians and the old Universities, has given to the humanities an important part in education, so that they have moulded a larger section of the profession than in any other country. A physician may possess the science of Harvey and the art of Sydenham, and yet there may be lacking in him these finer qualities of heart and head which count for so much in life. Pasture is not everything and that indefinable, though well understood, something which we know as breeding, is not always an accompaniment of great professional skill. Medicine is seen at its best in men whose faculties have had the highest and most harmonious culture. The Lathams, the Watsons, the Pagets, the Jenners, and the Gairdners have influenced the profession less by their special work than by exemplifying those graces of life and refinements of heart which make up character. And the men of this stamp in Greater Britain have left the most enduring mark,—Beaumont, Bovell and Hodder in Toronto; Holmes Campbell and Howard in this city; the Warrens, the Jacksons, the Bigelows, the Bowditches, and the Shattucks in Boston; Bard, Hossack, Francis, Clark and Flint of New York; Morgan, Shippen, Redman, Rush, Cox, the elder Wood, the elder Pepper, and the elder Mitchell of Philadelphia,—Brahmins all, in the language of the greatest Brahmin among them, Oliver Wendell Holmes,—these and men like unto them have been the heaven which has raised our profession above the dead level of a business.

The *literæ humaniores*, represented by Linacre, revived Greek methods; but the Faculty during the sixteenth and at the beginning of the seventeenth centuries was in a slough of ignorance and self-conceit, and not to be aroused even by Moses and the prophets in the form of Hippocrates and the fathers of medicine. In the pictures referred to, Sydenham is placed between Linacre and Harvey; but science preceded practice, and Harvey's great Lumleian lectures were delivered before Sydenham was born. Linacre has been well called, by Payne, Harvey's intellectual grandfather. "The discovery of the circulation of the blood was the climax of that movement which began a century and a half before with the revival of Greek medical classics, and especially of Galen" (Payne). Harvey returned to Greek methods and became the founder of modern experimental physiology and the great glory of British scientific medicine. The demonstration of the circulation of the blood remains in every detail a model research. I shall not repeat the oft-told tale of Harvey's great and enduring influence, but I must refer to one feature which, until lately, has been also a special characteristic of his direct successors in Great Britain. Harvey was a practitioner and a hospital physician. There are gossiping statements by Aubrey to the effect that "he fell mightily in his practice" after the publication of the "*De motu cordis*," and that his "therapeutic way" was not admired; but to these his practical success is the best answer. It is remarkable that a large proportion of all the physiological work of Great Britain has been done by men who have become successful hospital physicians or surgeons. I was much impressed by a conversation with Professor Ludwig in 1884. Speaking of the state of English physiology, he

lamented the lapse of a favorite English pupil from science to practice; but, he added, "while sorry for him, I am glad for the profession in England." He held that the clinical physicians of that country had received a very positive impress from the work of their early years in physiology and the natural sciences. I was surprised at the list of names which he cited; among them I remember Bowman, Paget, Savory and Lister. Ludwig attributed this feature in part to the independent character of the schools in England, to the absence of the University element so important in medical life in Germany, but, above all, to the practical character of the English mind, the better men preferring an active life in practice to a secluded laboratory career.

Thucydides it was who said of the Greeks that they possessed "the power of thinking before they acted, and of acting, too." The same is true in a high degree of the English race. To know just what has to be done, then to do it, comprises the whole philosophy of practical life. Sydenham — *Angliæ lumen*, as he has been well called, is the model practical physician of modern times. Linacre led Harvey back to Galen. Sydenham to Hippocrates. The one took Greek science, the other not so much Greek medicine as Greek methods, particularly intellectual fearlessness, and a certain knack of looking at things. Sydenham broke with authority and went to nature. It is an extraordinary fact that he could have been so emancipated from dogmas and theories of all sorts. He laid down the fundamental proposition, and acted upon it, that "all diseases should be described as objects of natural history." To do him justice we must remember, as Dr. John Brown says, "in the midst of what a mass of errors and prejudices, of theories actively mischievous, he was placed, at a time when the mania of hypothesis was at its height, and when the practical part of his art was overrun and stultified by vile and silly nostrums." Sydenham led us back to Hippocrates, I would that we could be led oftener to Sydenham! How necessary to bear in mind what he says about the method of the study of medicine. In writing therefore, such a natural history of diseases, every merely philosophical hypothesis should be set aside, and the manifest and natural phenomena, however minute, should be noted with the utmost exactness. The usefulness of this procedure cannot be easily overrated, as compared with the subtle inquires and trifling notions of modern writers, for can there be a shorter, or indeed any other way of coming at the morbid causes, or discovering the curative indications than by a certain perception of the peculiar symptoms? By these steps and helps it was that the father of physic, the great Hippocrates, came to excel, his theory being no more than an exact description or view of nature. He found that nature alone often terminates diseases, and works a cure with a few simple medicines, and often enough with no medicines at all. Well indeed has a recent writer remarked, "Sydenham is unlike every previous teacher of the principles and practice of medicine in the modern world." He, not Linacre or Harvey, is the model British physician in whom were concentrated all those practical instincts upon which we lay such stress in the Anglo-Saxon character.

The Greek faculty which we possess of thinking and acting has enabled us, in spite of many disadvantages, to take the lion's share in the great practical

advances in medicine. Three among the greatest scientific movements of the century have come from Germany and France. Bichat, Laennec and Louis laid the foundation of modern clinical medicine; Virchow and his pupils of scientific pathology; while Pasteur and Koch have revolutionized the study of the causes of disease; and yet, the modern history of the art of medicine could almost be written in its fulness from the records of the Anglo-Saxon race. We can claim every practical advance of the very first rank — vaccination, anesthesia, preventive medicine and antiseptic surgery, the "captain jewels in the carcanet" of the profession, beside which can be placed no others of equal lustre.

One other lesson of Sydenham's life needs careful conning. The English Hippocrates, as I said, broke with authority. His motto was

"Thou Nature art my Goddess; to thy law
My services are bound."

Undue reverence for authority as such, a serene satisfaction with the *status quo* and a fatuous objection to change have often retarded the progress of medicine. In every generation, in every country, there have been, and ever will be, *laudatores temporis acti*, in the bad sense of that phrase, not a few of them men in high places, who have lent the weight of a complacent conservatism to bolster up an ineffectual attempt to stay the progress of new ideas. Every innovator from Harvey to Lister has been made to feel its force. The recently-issued life of Thomas Wakley is a running commentary on this spirit, against the pricks of which he kicked so hard and so effectually. But there are signs of a great change. The old universities and the colleges, once the chief offenders, have been emancipated, and remain no longer, as Gibbon found them, steeped in port and prejudice. The value of authority *per se* has lessened enormously, and we of Greater Britain have perhaps suffered as the pendulum has swung to the other extreme. Practice loves authority, as announced in "the general and perpetual voice of men." Science must ever hold with Epicharmus that a judicious distrust and wise scepticism are the sinews of the understanding. And yet the very foundations of belief in almost everything relating to our art rest upon authority. The practitioner cannot always be the judge; the responsibility must often rest with the teachers and investigators, who can only learn in the lessons of history the terrible significance of the word. The fetters of a thousand years in the treatment of fever were shattered by Sydenham, shattered only to be riveted anew. How hard was the battle in this century against the entrenched and stubborn foe! Listen to the eloquent pleadings of Stokes, pleading as did Sydenham, against authority, and against the bleedings, the purgings and sweatings of fifty years ago. "Though his hair be gray and his authority high, he is but a child in knowledge and his reputation an error. On a level with a child, so far as correct appreciation of the great truths of medicine is concerned, he is very different in other respects, his powers of doing mischief are greater; he is far more dangerous. Oh! that men would stoop to learn, or at least cease to destroy." The potency of human authority among the powers that be, was never better drawn than by the judicious Hooker in his section on this subject. "And this not only with the simpler sort, but the learned and wiser we are, the more

such arguments in some cases prevail with us. The reason why the simpler sort are moved with authority is the conscience of their own ignorance; whereby it cometh to pass that having learned men in admiration, they rather feared to dislike them than know wherefore they should allow and follow their judgments. Contrariwise with them that are skilful authority is much more strong and forcible; because they only are able to discern how just cause there is why to some men's authority so much should be attributed. For which cause the name of Hippocrates (no doubt) were more effectual to persuade even such men as Galen himself than to move a silly empiric."²

Sydenham was called "a man of many doubts" and therein lay the secret of his great strength.

Passing now to the main question of the development of this British medicine in Greater Britain, I must at once acknowledge the impossibility of doing justice to it. I can only indicate a few points of importance, and I must confine my remarks chiefly to the American part of Greater Britain. We may recognize three distinct periods corresponding to three distinct waves of influence, the first from the early immigration to about 1820, the second from about 1820 to 1860, and the third from about 1860 to the present time.

The colonial settlements were contemporaneous with the revival of medicine in England. Fellow-students of Harvey at Cambridge might have sailed in the *Mayflower* and the *Arbella*. The more carefully planned expeditions usually enlisted the services of a well-trained physician, and the early records, particularly of the New England colonies, contain many interesting references to these college-bred men. Giles Firman, who settled in Boston in 1632, a Cambridge-man, seems to have been the first to give instruction in medicine in the New World. The parsons of that day had often a smattering of physic, and illustrated what Cotton Mather called an "angelical conjunction." He says: "Even since the days of Luke, the Evangelist, skill in *Physick* has been frequently professed and practised by Parsons whose more declared Business was the study of Divinity." Firman himself, finding physic "but a meane helpe," took orders. These English physicians in the New England colonies were scholarly, able men. Roger Chillingworth, in Hawthorne's "Scarlet Letter," has depicted them in a sketch of his own life: "Made up of earnest, studious, thoughtful, quiet years, bestowed faithfully for the increase of knowledge, faithfully, too, for the advancement of human welfare—men, thoughtful for others, caring little for themselves, kind, just, true and of constant if not warm affections"—a singularly truthful picture of the old colonial physician.

Until the establishment of medical schools (University of Pennsylvania, 1763; King's College [afterwards Columbia] 1767; Harvard, 1782), the supply of physicians for the colonies came from Great Britain, supplemented by men trained under the old apprentice system, and of colonists who went to Edinburgh, Leyden and London for their medical education. This latter group had a most powerful effect in moulding professional life in the pre-revolutionary period. They were men who had enjoyed not alone the instruction but often the intimate friendship of the great English and European physicians. Morgan, Rush, Shippin, Bard, Wistar, Hossack and others had received an education comprising all that was best in the period,

and had acquired the added culture which can only come from travel and wide acquaintance with the world. Morgan, the founder of the medical school of the University of Pennsylvania, was away seven years, and before returning had taken his seat as a corresponding member of the French Academy of Surgery, besides having been elected a Fellow of the Royal Society. The War of Independence interrupted temporarily the stream of students, but not the friendship which existed between Cullen and Fothergill and their old pupils in America. The correspondence of these two warm friends of the colonies testifies to the strong professional intimacy which existed at the time between the leaders of the profession in the Old and New Worlds.

But neither Boerhaave, Cullen nor Fothergill stamped colonial medicine as did the great Scotchman, John Hunter. Long, weary centuries separated Harvey from Galen; not a century elapsed from the death of the great physiologist to the advent of the man in whose phenomenal personality may be seen all the distinctive traits of modern medicine, and the range of whose mighty intellect has had few, if any, equals since Aristotle. Hunter's influence on the profession of this continent, so deep and enduring, was exerted in three ways. In the first place, his career as an army surgeon, and his writings on subjects of special interest to military men, carried his work and ways into innumerable campaigns in the long French wars and in the War of Independence. Hunter's works were reprinted in America as early as 1791 and 1793. In the second place, Hunter had a number of most distinguished students from the colonies, among whom were two who became teachers of wide reputation. William Shippin, the first Professor of Anatomy in the University of Pennsylvania, lived with Hunter on terms of the greatest intimacy. He brought back his methods of teaching and some measure of his spirit. With the exception of Hewson and Home, Hunter had no more distinguished pupil than Philip Syng Physick, who was his house surgeon at St. George's Hospital, and his devoted friend. For more than a generation Physick had no surgical compeer in America, and enjoyed a reputation equalled by no one save Rush. He taught Hunterian methods in the largest medical school in the country, and the work of his nephew (Dorsey) on surgery is very largely Hunter modified by Physick. But in a third and much more potent way the great master influenced the profession of this continent. Hunter was a naturalist to whom pathological processes were only a small part of a stupendous whole, governed by law, but which could never be understood until the facts had been accumulated, tabulated and systematized. By his example, by his prodigious industry and by his suggestive experiments he led men again into the old paths of Aristotle, Galen and Harvey. He made all thinking physicians naturalists, and he lent a dignity to the study of organic life, and re-established a close union between medicine and the natural sciences. Both in Britain and Greater Britain he laid the foundation of the great collections and museums, particularly those connected with the medical schools. The Wistar-Horner and the Warren museums originated with men who had been greatly influenced by Hunter. He was, moreover, the intellectual father of that interesting group of men on this side of the Atlantic who, while practising as physicians, devoted much time and labor

² Ecclesiastical Polity, Book II, vii, 2.

to the study of natural history. In the latter part of the last century and during the first thirty years of this, the successful practitioner was very often a naturalist. I wish that time permitted me to do justice to the long list of men who have been devoted naturalists and who have made contributions of great value. Benjamin Smith Barton, David Hossack, Jacob Bigelow, Richard Harlan, John D. Godman, Samuel George Morton, John C. Warren, Samuel L. Mitchell, J. Aiken Meigs and many others have left the records of their industry in their valuable works and in the *Transactions* of the various societies and academies. In Canada, many of our best naturalists have been physicians, and collections in this city testify to the industry of Holmes and McCulloch.

I was regretting the *humanities* a few moments ago, and now I have to mourn the almost complete severance of medicine from the old natural history. To a man the most delightful recollections of whose student life are the Saturdays spent with a perceptor who had a Hunterian appetite for specimens—anything from a trilobite to an acarus—to such a one across the present brilliant outlook comes the shadow of the thought that the conditions of progress will make impossible again such careers as those of William Kitchen Parker and William Carmichael McIntosh.

Until about 1820 the English profession of this continent knew little else than British medicine. After this date in the United States the ties of professional union with the old country became relaxed, owing in great part to the increase in the number of home schools, and in part to the development of American literature. To 1820 one hundred and fourteen native medical books of all kinds had been issued from the press, and one hundred and thirty-one reprints and translations, the former English, the latter, few in number, and almost exclusively French (Billings).

Turning for a few minutes to the condition of the profession in Canada during this period, I regret that I cannot speak of the many interesting questions relating to the French colonies. With the earliest settlers physicians had come, and among the Jesuits, in their devoted missions, there are records of *donnés* (laymen attached to the service), who were members of the profession. One of these, René Goupil, suffered martyrdom at the hands of the Iroquois.³

Between the fall of Quebec in 1759 and 1820, the English population had increased by the settlement of Upper Canada, chiefly by United Empire Loyalists from the United States, and after the War of 1812 by settlers from the Old Country. The physicians in the sparsely settled districts were either young men who sought their fortunes in the new colony or were army surgeons, who had remained after the Revolutionary War or the War of 1812. The military element gave for some years a very distinctive stamp to the profession. These surgeons were men of energy and ability, who had seen much service, and were accustomed to order, discipline and regulations. Sabine, in his "History of the Loyalists," refers to the Tory proclivities of the doctors, but says that they were not so much disturbed as the lawyers and clergymen. Still a good many of them left their homes for conscience sake, and Canniff, in his "History of the Profession in Upper Canada," gives a list of those known to have been among the United Empire Loyalists.

The character of the men who controlled the pro-

fession of the new colony is well shown by the proceedings of the Medical Board which was organized in 1819. Drs. Macaulay and Widmer, both army surgeons, were the chief members. The latter, who has well been termed the father of the profession in Upper Canada, a man of the very highest character, did more than any one else to promote the progress of the profession; and throughout his long career his efforts were always directed in the proper channels. On looking through Canniff's most valuable work one is much impressed by the stirring worth and mettle of these old army surgeons who in the early days formed the larger part of the profession. The minutes of the Medical Board indicate with what military discipline the candidates were examined, and the percentage of rejections has probably never been higher in the history of the province than it was in the first twenty years of the existence of the Board.

One picture on the canvas of those early days lingers in the memory, illustrating all the most attractive features of a race which has done much to make this country what it is to-day. Widmer was the type of the dignified old army surgeon, scrupulously punctilious and in every detail regardful of the proprieties of life. "Tiger" Dunlop may be taken as the very incarnation of that restless, roving spirit which has driven the Scotch broadcast upon the world. After fighting with the Connaught Rangers in the War of 1812, campaigning in India, clearing the Sangar of tigers—hence his soubriquet "Tiger," lecturing on Medical Jurisprudence in Edinburgh, writing for *Blackwood*, editing the *British Press* and the *Telescope*, introducing Beck's Medical Jurisprudence to English readers, and figuring as director and promoter of various companies, this extraordinary character appears in the young colony as "Warden of the Black Forest" in the employ of the Canada Company. His life in the backwoods at Gairbraid, his "Noctes Ambrosianae Canadensis" his famous "Twelve Apostles" as he called his mahogany liquor stand (each bottle a full quart), his active political life, his remarkable household, his many eccentricities—are they not all portrayed to the life in the recently issued "In the Days of the Canada Company"?

Turning now to the second period, we may remark in passing that the nineteenth century did not open very auspiciously for British medicine. Hunter had left no successor, and powerful as had been his influence it was too weak to stem the tide of abstract speculation, with which Cullen, Brown and others flooded the profession. No more sterile period exists than the early decades of this century. Willan (a great naturalist in skin diseases) with a few others saved it from utter oblivion. The methods of Hippocrates, of Sydenham, and of Hunter had not yet been made available in everyday work.

The awakening came in France, and such an awakening! It can be compared with nothing but the renaissance in the sixteenth and seventeenth centuries, which gave us Vesalius and Harvey. "Citizen" Bichat and Broussais led the way, but Laennec really created clinical medicine as we know it to-day. The discovery of auscultation was only an incident, of vast moment it is true, in a systematic study of the correlation of symptoms with anatomical changes. Louis, Andral and Chomel, extended the reputation of the French school which was maintained to the full until the sixth decade, when the brilliant Trousseau ended for a time

³ Parkman: Jesuits in North America.

a long line of Paris teachers, whose audience had been world wide. The revival of medicine in Great Britain was directly due to the French. Bright and Addison, Graves and Stokes, Forbes and Marshall Hall, Latham and Bennett were profoundly affected by the new movement. In the United States Anglican influence did not wane until after 1820. Translations of the works of Bichat appeared as early as 1802, and there were reprints in subsequent years, but it was not until 1823 that the first translation (a reprint of Forbes's edition) of Lennec was issued. Broussais' works became very popular in translations after 1830, and in the journals from this time on the change of allegiance became very evident. But men rather than books diverted the trend of professional thought. After 1825, American students no longer went to Edinburgh and London, but to Paris, and we can say that between 1830 and 1860, every teacher and writer of note passed under the Gallic yoke. The translations of Louis's works and the extraordinary success of his American pupils, a band of the ablest young men the country had ever seen, added force to the movement. And yet this was a period in which American medical literature was made up largely of pirated English books, and the systems, encyclopedias and libraries, chiefly reprints, testify to the zeal of the publishers. Stokes, Graves, Watson, Todd, Bennett and Williams, furnished Anglican pap to the sucklings, as well as strong meat to the full grown. In spite of the powerful French influence the text-books of the schools were almost exclusively English.

In Canada the period from 1820 to 1860 saw the establishment of the English universities and medical schools. In Montreal the agencies at work were wholly Scotch. The McGill Medical School was organized by Scotchmen, and from its inception has followed closely Edinburgh methods. The Paris influence, less personal, was exerted chiefly through English and Scotch channels. The Upper Canada schools were organized by men with English affiliations, and the traditions of Guy's, St. Bartholomew, St. Thomas, St. George's, and of the London Hospital, rather than those of Edinburgh, have prevailed in Toronto and Kingston.

The local French influence on British medicine in Canada has been very slight. In the early decades of the century, when the cities were smaller, and the intercourse between the French and English somewhat closer, the reciprocal action was more marked. At that period English methods became somewhat the vogue among the French; several very prominent French Canadians were Edinburgh graduates. Attempts were made in the medical journals to have communications in both languages, but the fusion of the two sections of the profession was no more feasible than the fusion of the two nationalities, and the development has progressed along separate lines.

The third period dates from about 1860 when the influence of German medicine began to be felt. The rise of the Vienna school was for a long time the only visible result in Germany of the French renaissance. Skoda, the German Lennec, and Rokitsansky, the German Morgagni, influenced English and American thought between 1840 and 1860, but it was not until after the last date that Teutonic medicine began to be felt as a vitalizing power, chiefly through the energy of Virchow. After the translation of the "Cellular Pathology" by Chance (1860) the way lay clear and

open to every young student who desired inspiration. There had been great men in Berlin before Virchow, but he made the town on the Spree a Mecca for the faithful of all lands. From this period we can date the rise of German influence on the profession of this continent. It came partly through the study of pathological histology, under the stimulus given by Virchow, and partly through the development of the specialties, particularly diseases of the eye, of the skin and of the larynx. The singularly attractive courses of Hebra, the organization on a large scale in Vienna of a system of graduate teaching designed especially for foreigners, and the remarkable expansion of the German laboratories combined to divert the stream of students from France. The change of allegiance was a deserved tribute to the splendid organization of the German universities, to the untiring zeal and energy of their professors and to their single-minded devotion to science for its own sake.

In certain aspects the Australasian Settlements present the most interesting problems of Greater Britain. More homogeneous, thoroughly British, isolated, distant, they must work out their destiny with a less strigent environment than, for example, surrounds the English in Canada. The traditions are more uniform and of whatever character have filtered through British channels. The professional population of native-trained men is as yet small, and the proportion of graduates and licentiates from the English, Scotch and Irish colleges and boards guarantees a dominance of Old Country ideas. What the maturity will show cannot be predicted, but the vigorous infancy is full of crescent promise. On looking over the files of Australian and New Zealand journals, one is impressed with the monotonous similarity of the diseases in the antipodes to those of Great Britain and of this continent. Except in the matter of parasitic affections and snake-bites, the nosology presents few distinctive qualities. The proceedings of the four Intercolonial Congresses indicate a high level of professional thought. In two points Australia has not progressed as other parts of Greater Britain. The satisfactory regulation of practice, so early settled in Canada, has been beset with many difficulties. Both in the United States and in Australia the absence of the military element, which was so strong in Canada, may in part at least account for the great difference which has prevailed in this matter of the State license. The other relates to the question of ethics, to which one really does not care to refer, were it not absolutely forced upon the attention in reading the journals. Elsewhere professional squabbles, always so unseemly and distressing, are happily becoming very rare, and in Great Britain, and on this side of the water, we try at any rate "to wash our dirty linen at home." In the large Australian cities, differences and dissensions seem lamentably common. Surely they must be fomented by the atrocious system of elections to the hospitals, which plunges the entire profession every third or fourth year into the throes of a contest, in which the candidates have to solicit the suffrages of from 2,000 to 4,000 voters! Well, indeed, might Dr. Batchelor, in his address at the Fourth Intercolonial Congress, say: "It is a scandal that in any British community, much less in a community which takes pride in a progressive spirit, such a pernicious system should survive for an hour."

Of India, of "Visnu-land," what can one say in a

few minutes? Three thoughts at once claim recognition. Here in the dim dawn of history, with the great Aryan people, was the intellectual cradle of the world. To the Hindoos we owe a debt which we can at any rate acknowledge; and even in medicine, many of our traditions and practices may be traced to them as may be gathered from that most interesting "History of Aryan Medical Science," by the Thakore Sahab of Gondal.

Quickly there arises the memory of the men who have done so much for British medicine in that great empire. Far from their homes, far from congenial surroundings, and far from the stimulus of scientific influences, Annesley, Ballingall, Twining, Morehead, Waring, Parkes, Cunningham, Lewis, Vandyke Carter, and many others, have upheld the traditions of Harvey and of Sydenham. On the great epidemic diseases how impoverished would our literature be in the absence of their contributions! But then there comes the thought of "the petty done, the undone vast," when one considers the remarkable opportunities for study which India has presented. Where else in the world is there such a field for observation in cholera, leprosy, dysentery, the plague, typhoid fever, malaria and in a host of other less important maladies? And what has the British Government done towards the scientific investigation of the diseases of India? Until recently little or nothing, and the proposal to found an institute for the scientific study of disease has actually come from the native chiefs! The work of Dr. Hankin and of Professor Haffkine, and the not un-mixed evil of the British epidemic of plague in Bombay, may arouse the officials to a consciousness of their shortcomings. While sanitary progress has been great as shown in a reduction of the mortality from 69 per mille before 1857 to 15 per mille at present, many problems are still urgent, as may be gathered from reading Dr. Harvey's Presidential Address and the Proceedings of the Indian Medical Congress. That typhoid fever can be called the "scourge of India" and that the incidence of the disease should remain so high among the troops point to serious sanitary defects as yet unremedied. As to the prevalence of venereal disease among the soldiers — an admission of nearly 500 per mille tells its own tale. On reading the journals and discussions, one gets the impression that matters are not as they should be in India. There seems to be an absence of proper standards of authority. Had there been in each presidency during the past twenty years thoroughly equipped government laboratories in charge of able men, well trained in modern methods, the contributions to our knowledge of epidemic diseases might have been epoch-making, and, at any rate, we should have been spared the crudeness which is evident in the work (particularly in that upon malaria), of some zealous but badly-trained men.

In estimating the progress of medicine in the countries comprising Greater Britain, the future rather than the present should be in our minds. The strides which have been taken during the past twenty years are a strong warrant that we have entered upon a period of exceptional development. When I see what has been accomplished in this city in the short space of time since I left, I can scarcely credit my eyes: the reality exceeds the utmost desire of my dreams. The awakening of the profession in the United States to a consciousness of its responsibilities and opportunities has caused unparalleled changes, which have given an

impetus to medical education and to higher lines of medical work which has already borne a rich harvest. Within two hundred years who can say where the intellectual centre of the Anglo-Saxon race will be? The Mother Country herself has only become an intellectual nation of the first rank within a period altogether too short to justify a prediction that she has reached the zenith. She will probably reverse the history of Hellas, in which the mental superiority was at first with the colonies. At the end of the next century, ardent Old-World students may come to this side "as o'er a brook," seeking inspiration from great masters, perhaps in this very city; or the current may turn towards the schools of the great nations of the south. Under new and previously unknown conditions, the Africander, the Australian or the New Zealander may reach a development before which even "the glory that was Greece" may pale. Visionary as this may appear, it is not one whit more improbable to-day than would have been a prophecy made in 1797 that such a gathering as the present would be possible within a century on the banks of the St. Lawrence.

Meanwhile, to the throbbing vitality of modern medicine the two great meetings held this month, in lands so widely distant, bear eloquent testimony. Free, cosmopolitan, no longer hampered by the dogmas of schools, we may feel a just pride in a profession almost totally emancipated from the bondage of error and prejudice. Distinctions of race, nationality, color and creed are unknown within the portals of the temple of Æsculapius. Dare we dream that this harmony and cohesion so rapidly developing in medicine, obliterating the strongest lines of division, knowing no tie of loyalty but loyalty to truth — dare we hope, I say, that in the wider range of human affairs a similar solidarity might ultimately be reached? Who can say that the forges of Time will weld no links between man and man stronger than those of religion or of country? Some Son of Beor, touched with prophetic vision, piercing the clouds which now veil the eternal sunshine of the mountain top — some spectator of all time and all existence (to use Plato's expression) — might see in this gathering of men of one blood and one tongue a gleam of hope for the future, of hope at least that the great race so dominant on the earth to-day may progress in the bonds of peace — a faint glimmer perhaps of the larger hope of humanity, of that day when "the common-sense of most shall hold a fretful world in awe." There remains for us, Greater Britains of whatsoever land, the bounden duty to cherish the best traditions of our fathers, and particularly of the men who gave to British medicine its most distinctive features, of the men, too, who found for us the light and liberty of Greek thought — Linacre, Harvey and Sydenham, those ancient founts of inspiration and models for all time in Literature, Science and Practice.

It is said that Dr. H. R. Silvester, whose discovery of a method of restoring persons after apparent cessation of respiration has saved many hundreds of lives, has received no adequate personal reward or distinction for the great benefit he rendered humanity. The only recognition which Dr. Silvester has received is the presentation of the Fothergill medallion awarded him by the Royal Humane Society, which, although a high honor, is not distinction enough for the important services rendered. — *Medical News*.

THE SCHOLAR IN MEDICINE.¹

BY J. M. DA COSTA, M.D., LL.D. (HARV.).

MR. PRESIDENT OF THE UNIVERSITY, MR. PRESIDENT OF THE HARVARD MEDICAL ALUMNI ASSOCIATION, ALUMNI OF HARVARD:—When you, Mr. President of the Association, asked me to address this distinguished gathering, I begged that it be not on the subject of medical education, which, with all its great interests, had been for the present exhausted by the many who have treated of it before you so well and so often. I then thought that, in place of considering those whose minds are still to be moulded, it might be not inappropriate to give our attention to those fully formed; and so, with your permission, I will say a few words in regard to one of the very best types of these we meet,—the scholar in medicine. It is particularly fitting that I should do so here, while speaking in a city that is justly proud of its general culture, and under the shadow of the great university to which you all belong, to a profession that has been always distinguished for its love and appreciation of scholarship. It is fitting, surely, to speak of scholars to the pre-eminently scholarly profession of Boston.

In mentioning the scholars in medicine, I shall refer more particularly to those who have been men of cultivation and mental training other than merely in their own line, who, while actively pursuing their profession and learned in it, were not learned in it alone. I mean the men who, whether distinguished in the older restricted sense of scholarship chiefly in the classics, or in the much more comprehensive modern sense of general knowledge and culture in many and diversified branches, carry with them into professional life zest for these studies and the attitude of mind they give. I mean in its fullest sense the general scholar in medicine. Nor is it the scholar who has been a physician, but has largely or entirely abandoned his profession to devote himself to scholarship, and has been chiefly known through this and his general knowledge, that I am speaking of, though here there would be a noted list to enumerate.

Here is, in comparatively recent years, Adams, whose translations of Hippocrates and of Paulus Ægineta are admirable; here is Greenhall, of Oxford, deeply versed in Arabic lore; here are Bussemaker and Daremberg, the profound scholars, whose Oribasius and other editions of Greek and Latin classics critics everywhere laud. Here is Littré, the celebrated Greek student, who has also produced the best dictionary in any living tongue, and, unaided, has done for the French language in one lifetime what the French Academy has not accomplished since its creation.

And in older generations we find Linaere, court physician to Henry VIII, envoy, founder of the College of Physicians, the matchless teacher of Greek, having Erasmus among his pupils, the translator of Galen and of Aristotle into Latin so pure and grace-

ful that it was the admiration of his age; Caius, the benefactor of Caius College, Cambridge, the nine-times elected President of the College of Physicians, the physician to Queen Elizabeth, spoken of by Gesner in an epistle to her as the most learned physician of his age, and regarded as being the superior of any man of his time in Europe in profound knowledge of Greek, which he, while pursuing his anatomical studies at Padua, taught as public professor, and always insisted should be pronounced after the manner of modern Greeks. There is the great thinker, Locke, who to the last liked to dabble in medicine and practise on his friends, not always to their pleasure or advantage; also Sir Thomas Browne, though court physician, yet chiefly known by his extraordinary erudition that shows so conspicuously in the "Religio Medici" and "Urn Burial," and in the quaint conceits of his other writings, who could not, however, have been a very good companion, for it is recorded of him in Dr. Johnson's Life that, though always cheerful, he was rarely merry, "seldom heard to break a jest, and, when he did, he would be apt to blush at the levity of it," unmindful that Bacon himself dictated from memory in a single day a jest book which Macaulay has pronounced the best in the world. Further, there is Rabelais, the inimitable humorist of France, who, after taking his doctor's degree at Montpellier, lectured publicly on Galen and Hippocrates. But I will not dwell on him, since it is in literature rather than in learning that lies his fame. To dwell on him, too, would bring up forcibly the image of one who resembled him, and revive keenly the sense of the loss of the scholar, critic, man of letters, whose good-natured laughter resounded through the world,—our own Oliver Wendell Holmes.

Nor will I say anything of the host of physicians that have been distinguished in pursuits different from those we ordinarily class with scholarship, such as wide knowledge and research in the natural sciences; though I cannot forbear to mention Galvani, the doctor of Bologna; and Linnaeus, the physician at Stockholm, the professor at Upsala, whose classes his fame trebled; and another renowned Swede, the illustrious chemist, Berzelius; and Young, the Professor of Natural Philosophy at the Royal Institute, who, besides his extensive knowledge in mathematics, natural philosophy and botany, was master of many modern languages, and of Latin, Greek, Chaldee, Arabic, Syriac, Hebrew, Persian and Samaritan; and of Black, the popular physician at Glasgow, the discoverer of latent heat; and your celebrated botanist, Gray; and the great naturalist of varied acquirements, the father of popular scientific education in America, one of the glories of Harvard—Agassiz; and another of our great countrymen, Leidy, that man of deep knowledge of everything appertaining to the natural sciences.

But to turn to the men who have been famed in their profession as well as admirable scholars, and whose traits of mind were essentially those of the scholar. It is interesting how some of the illustrious names in medicine appear in evidence. Harvey is conspicuous—Harvey, whose style is so limpid and clear that whatever he states becomes at once a demonstration, and grace and propriety mark every utterance. He is the Cambridge scholar all his life, as well as the great physiologist and physician. Boerhaave, the high-minded professor and physician, the man of many

¹ Remarks made at the Annual Meeting of the Harvard Medical Alumni Association, June 29, 1897, by Dr. Da Costa, who was introduced by the President of the Association, Dr. Geo. B. Shattuck, in these words:

"Four years ago Dr. Da Costa was good enough to come from Philadelphia to help us at our meeting in a discussion of some of the problems of medical education. This year Harvard College requested his presence at Cambridge on Commencement Day, which means, it is permitted to suppose, still another bond of union. Under these circumstances he kindly consented to become our guest again. You have known Dr. Da Costa, of Philadelphia; and you want to know Dr. Da Costa, of Cambridge, a wise physician, whose name is inseparably associated with medical diagnosis, a sound scholar."

accomplishments, of extraordinary simplicity and kindness, thinking nothing of lecturing five hours daily, making the University of Leyden more famous than it had ever been, attracting patients from all parts of the world, among them, though as pupil rather than as patient, Peter the Great, — he, too, was all his life the diligent, accomplished scholar. So was Mead, the renowned and most popular physician of the time of George II, a Mæcenas in literature and art, a beneficent and kindly social power, finished writer, ardent mathematician. The renowned professor of Padua, Morgagni, was also widely known as a practising physician, of whose art he must have possessed some of the best qualifications. "*Adeo erat in observando attentus, in prædicendo cautus, in curando felix,*" is recorded of him; and I see you smile at the *prædicendo cautus*, the caution in prognosis, — a trait it is thought his successors have not lost. He was very popular with his colleagues, and taught until he was ninety-one years of age, whether to the edification of those who looked to succeeding him in his chair is not recorded. Throughout his long life he was a great scholar as well as original thinker, was noted for the elegance of his Latin style, which shows to the last in his splendid work, "*De Sedibus et Causis Morborum,*" published in his eightieth year. A further marked illustration of the scholar among famed physicians is furnished by Lænnec, the founder of modern diagnosis. He was an excellent writer and a most accomplished Greek scholar. Of this, indeed, and of his horsemanship, he was more proud than of his amazing additions to science. The noted American physician, Rush, too, was much more than a medical author and practitioner. Deeply interested in public affairs, he was also known as hospital physician and professor, as philanthropist, essayist, and philosopher, and was of activities so widely recognized that the National Institute of France enrolled him among its members.

In the illustrations given of renowned physicians who were also noted for their scholarship, I have selected, among many, those of the greatest pre-eminence belonging to times remote from our own. But, without mentioning the living, — and Virchow and Paget, those masters of clear thought and purest language, are still among us, — it would not be difficult to point to examples nearer our own time that worthily uphold the best medical traditions as regards scholarly attainments. It is only necessary to speak of Simpson, archæologist and discoverer, of Brodie, philosopher as well as admirable writer, of Latham, incisive writer of pure English, of Watson, whose style makes him rank among the classics of the Victorian era, of Trousdale, the eloquent master of French prose, of Malgaigne, the erudite surgeon, of Sée, the medical orator, of Douglass, the great lexicographer, of Billroth, the many-sided teacher, of Hyrtl, one of the most accomplished of modern scholars, and wonderful linguist as well as illustrious professor, to make clear how scholarship and broad attainments have steadily remained in the medical profession.

The scholarship I have been commenting on is the common scholarship of cultivated men, — general culture and knowledge, and not professional scholarship or learning. But, where in a professional man the former exists, he is sure also to possess the latter. Scholarship in broad lines brings with it learning in special lines. The habits and tastes of the scholar, and his mental attitude, remain the same, whether in

or out of his avocation. And, when we speak of the scholar in medicine, it is to be inferred almost with certainty that he is learned in his profession as well as out of it.

The love of intellectual cultivation is wide-spread in the profession. Let us not suppose that it is only found in medical centres or among those whom the profession recognize as their leaders. You may come across the scholar where you do not look for him. Twice this has happened to me recently. On one of these occasions I found him, in a small village, in a country practitioner, as an admirable Greek scholar, as well as of marked learning in his profession; another time, in a small country town, I met him in one who displayed a knowledge of old English and the changes that time had produced in our language that was amazing, and gave an hour of delightful talk after our medical conference was over.

In this utilitarian age the question may arise: What is the use of the scholar in medicine? We have obvious need for the investigator; but what is there for the scholar to do? Now there is no doubt that the investigator and originator in a science like medicine, with its tremendous problems and tremendous issues, is always of the first importance. And, if there is to be a choice between the scholar and the investigator, if a man can be only one, let the choice be always for the latter. — for the Parés, the John Hunters, the Jenners, the Marion Simses. But there need be no choice: the qualities may coexist, as proved by Harvey, Sydenham, Morgagni, Lænnec, and Lister, and lend accuracy and strength to the results obtained by the searcher in Nature's realm. The scholar has, indeed, great uses in medicine. Besides the power of expression, which comes, as a rule, with scholarship, he carries into every research, and into the estimate of every research, the facilities and critical judgment of a trained mind. He was never more needed than now, when every atom of discovery is heralded as of prodigious importance, and as sure to influence immediately the laws of the universe. It is the scholar who keeps the sense of proportion and fitness of everything, and who is not carried away into the maelstrom of pretence and assumption. It is the scholar who links the most valuable of the past to the most valuable of the present, understands and guards best against the errors of centuries, reads best the encouraging signs of the times and the bright hopes of the future. It is the scholar whose knowledge teaches him to appreciate correctly the different fads and isms which are constantly cropping up, and which he recognizes as old errors with new faces, susceptible, perhaps, of rational explanation; who traces in faith cures and kindred matters the history of expectant attention; who is able even to appreciate the value of cures by the seventh son of the seventh son. Do not think that this luminary is extinct. I know you can still find him in a place not forty miles from one of our largest cities, as a popular practitioner with a very long beard. He holds his chief medical séances on the first Friday of the new moon, cures by laying on hands, except in very bad cases, to which he administers some broth claimed to be of supernatural brewing, and which is particularly valuable in fits.

It is the love of true knowledge and progress on the part of the scholar, and his reverence for the lessons of the past, that counteracts all that is baneful in the tendencies to hasty generalization and unproved state-

ment. He is not carried away by mere assertion: he looks to experience and to the logic of facts. He appreciates at their true value the claims made for the host of new remedies daily introduced, the majority of which, if we wish to cure with, we must use while they are new. The scholarship that makes broadness also counteracts the worst feature in specialism. — to divide the profession into sections, marring its unity and strength. It is the scholar who maintains the ideal of his calling, who is the agreeable companion, by whom men in other professions estimate and appreciate the worth of ours. It is the scholar who founds libraries, does everything to promote collections and workshops of thought, and keeps his life free from the taint of barrenness. It is the scholar who cements the profession into the best of brotherhoods. It is the scholar who in a community creates an atmosphere of learning and appreciation of learning, which is apt to remain as an heirloom in families, forming scholarly clans, to the great advantage of the Commonwealth; and where could I find a better illustration of this than here in the home of the Warrens, the Jacksons, the Bowditches, the Bigelows, the Putnams and the Shattucks?

Moreover, it is the scholar through whom we are linked with sympathetic interest to other pursuits. To recall the noble words of Cicero, "Omnes artes quae ad humanitatem pertinent, habent quoddam commune vinculum, et quasi cognatione quadam inter se continentur." It is the scholar with his widespread sympathies who is the near of kin in this blood-relationship of all the arts, and who represents us in the universal domain of knowledge.

The scholar in medicine is, indeed, an attractive figure. We see him pursuing what noble ends, ambitious for what lofty recompenses, passing from life's beginning to its end through what scenes of sustained pleasure, — not grasping and scrambling for petty prizes or fleeting reputation and wealth, but aiming only at lofty objects. Such is the history, such the life of the scholar in medicine, as in every other branch of knowledge. If, mindful of the friendly and social character of this meeting, I have treated of a grave and serious subject, and thus temporarily interrupted your pleasure, you must excuse me. But the memory of the famed men of your great university, its traditions, its spirit, its atmosphere of learning and of scholarship, proved irresistible, and caused me to speak, and to speak longer than may have been fitting, on a subject that the circumstances suggested, and with which I know you are in thorough accord.

PALLIATIVE AND OPERATIVE TREATMENT OF FISTULA IN ANO.¹

BY JOHN B. BLAKE, M.D., BOSTON.

FISTULA in Ano is, next to hemorrhoids, the commonest of the diseases of the rectum, and is one of the minor surgical conditions with which the surgeon is most frequently confronted. It varies extremely in etiology, extent and symptomatology. It affects all ages and all classes, and for obvious reasons is often of months, or even years, duration before being brought

to the attention of the surgeon. It is more frequent in males than in females. An examination of the records of the Boston City Hospital shows that cases have been operated upon in that institution from one year to seventy-five years of age; these extreme limits are rare, and children are seldom afflicted with fistula. Of 100 cases recently operated at the Boston City Hospital, three were in patients less than twenty years old; 42 were between twenty and thirty years; 26 between thirty and forty years; 17 between forty and fifty years; and 12 were more than fifty. Sixty-eight per cent., therefore, were between the ages of twenty and forty; and the disease is most common, or at all events it seeks treatment most commonly, between these ages.

DEFINITION.

Gant defines fistula in ano as a "non-granulating sinus of the ischio-rectal fossa, usually with two openings." It need not necessarily open into the rectum, though it usually does so, and it is almost always in relation to the rectal walls.

ETIOLOGY.

By far the commonest cause of fistula is an inflammatory process, originating in the rectum or its neighborhood; that is, a proctitis, peri-proctitis, or an ischio-rectal abscess. Certain English writers assert that these are the only causes. This, however, is not true. Among other causes are fissures and ulcerated hemorrhoids, tubercular processes of rectum or ischio-rectal fossa, trauma, foreign bodies, such as fish bones, necrosis of sacrum or coccyx, and worms, especially in children. Finally, there are causes which should perhaps, be classified as predisposing rather than exciting, such as constipation, or alternate constipation and diarrhea, lack of cleanliness, and the heat and congestion and atony which the softness of cushions and modern chairs and the frequency of the sitting posture tend to develop in this region. Many surgeons believe this latter to be a fruitful source of fistula and hemorrhoids.

VARIETY AND TYPES.

It is not necessary to do more than mention the commoner types of fistula, such as the *complete*, the *blind internal* and the *blind external*. The rarer forms may be briefly described.

A horse-shoe fistula is one which extends to a greater or less degree on both sides of the anus, and usually opens into it in one or more places. It most commonly passes behind the anus. Its shape is due simply to the peculiar burrowing course of the pus. *Complete internal* and *complete external* are names given to fistulae with two openings, both of which are situated inside the rectum in the first case, and outside it in the second. Certain writers describe complete fistulae anatomically as *anal* and *rectal*, the former opening into the bowel low down, the latter at the level of, or above, the internal sphincter.

EXTENT.

Fistulae differ enormously in extent. Length, depth, direction, branching, inter-communications, and relations to anatomical landmarks, all vary within extreme limits. All degrees are found, from a single external opening to a series of sinuses which riddle the ischio-rectal fossa, or break into the rectum, bladder or vagina. The difference between extreme types

¹ Read before the Massachusetts Medical Society, June 9, 1897, and recommended for publication by the Society.

is enormous. The superficial fistula which involves only the margin of the external sphincter differs as much from one which has perforated the levator ani muscle, and invaded the pelvis, as does a mild catarrhal appendicitis from a fulminating case; and the severity of the operation and the length of convalescence vary accordingly.

SYMPTOMS.

The symptoms are usually unmistakable and the diagnosis obvious; but the precise determination of the extent of a fistula can never be made with certainty until the operation. Neither the duration of the symptoms, nor their intensity, nor the position or number of the orifices, can be depended upon as unerring guides in this regard. It is for this reason often impossible to give a definite prognosis before the operation.

Blind internal fistulæ are often as hard to diagnose as to demonstrate. Symptoms are often vague, and are usually soreness and a dragging sensation in the rectum at a varying distance from the anus, and a dull burning pain, usually increased after defecation. There may or may not be a discharge from the rectum. On digital or visual examination it is often impossible to demonstrate an opening. Such a fistula may accompany hemorrhoids, prolapse, or even fissure, unsuspected by the patient.

ANATOMY.

Anatomical considerations modify the treatment, and may at times dictate it. The important landmarks will, therefore, be briefly described.

The perineum is a rhomboidal area, of which the inferior edge of the symphysis pubis, and the coccyx, form the anterior and posterior extremities, and the tuberosities of the ischium, the lateral angles. The great sacro-sciatic ligaments extend from the tuberosities to the coccyx, making the posterior sides of the rhomboid, and the rami of the ischium and pubes form the anterior sides. The anterior half of this region is usually described as the perineum proper, and the posterior half as the ischio-rectal fossa. The roof is formed by the levator ani muscle, which is also the floor of the pelvic cavity.

The rectum is usually described in three parts, of which only the second and third are concerned in fistula. The second part begins at the top of the fourth sacral vertebra and extends to the upper margin of the internal sphincter. It rests upon the anterior surface of the sacrum, and is concave forward nearly to its lower extremity, where it turns abruptly backward over the lower end of the coccyx. Within it is sacculated and presents most of the anatomical characteristics of the large intestine. It is partially covered with peritoneum which extends further down on its anterior than on its posterior aspect, and finally leaves the rectum in the male about one inch above the edge of the prostate. In front of the rectum is the bladder in the male, and the vagina in the female. The depth of the pouch of the peritoneum in front of the rectum varies in different individuals, and at different times in the same individual, being higher when the bladder and rectum are full. In rare cases it may come close down to the prostate. This must be born in mind when following up a deep anterior fistula.

The third part of the rectum, or anal canal, is straight and directed backward and a little downward.

In life it is a slit, the walls held snugly in contact by the sphincters. The anus itself is elliptical, more so in males than in females, its long diameter being antero-posterior. In the female it is usually smooth and funnel-shaped, and free from hair; in the male it is wrinkled and covered with hair. Just beneath the skin at its margin are the thin radiating fibres of the corrugator cutis ani.

The external sphincter is elliptical, and is attached behind to the coccyx and in front to the tendinous centre of the perineum. In the female the fibres decussate anteriorly, and are continuous forward with the sphincter vaginae. It is a thin, flat muscle, and not a true sphincter. It closes the anus rather by approximating its lateral walls than by a circular contraction. It also pulls the coccyx forward, or helps to anchor the tendinous centre of the perineum.

The internal sphincter is a firm, thick rim of muscular fibres, produced by the increased development of the circular fibres of the rectum. It is a muscle of great strength, and upon its integrity depends the effective closing of the bowel. It is from one-half to one inch in depth, and is not connected with any bony landmark.

The levator ani is an important muscle forming the roof of the ischio-rectal fossa and the floor of the abdominal cavity, and has been not inaptly called the diaphragm of the pelvis. The rectum passes through it at its lowest point in somewhat the same manner that the esophagus passes through the diaphragm. The levator ani arises anteriorly from the back of the pubes, posteriorly from the spine of the ischium, and laterally from the so-called white line of the obturator fascia which connects these two. From this broad origin the fibres pass downward, backward and inward, to the tip of the coccyx, the sides of the rectum and the sides of the prostate or vagina. On the superior surface, only the pelvic fascia is interposed between it and the peritoneum. As it forms the roof of the ischio-rectal fossa, and slopes downward, it is obvious that the fossa is deepest away from the rectum, and becomes progressively shallower as the anus is approached. The action of the muscle is to lift the anus and second part of the rectum after it has been lowered or everted in defecation. It is also a muscle of forced respiration, and a landmark of extreme importance in the operation for fistula.

BLOOD-SUPPLY.

The blood-supply is from several sources, but mainly from the inferior hemorrhoidal branches of the internal pudic, and the middle hemorrhoidal of the internal iliac as well as the superficial and transverse perineal arteries.

The veins form the hemorrhoidal plexus, and are numerous and large. They are without valves, and are prone to become varicose.

The congestion of the region is increased by its anatomical position and by the character of these veins.

It is necessary to mention the deep and superficial perineal fascia, and the triangular ligament before leaving this subject, as it sometimes happens that a deep fistula burrowing anteriorly through the levator ani muscle comes to lie above this ligament, and has been known to dissect its way anteriorly and actually point into the thigh.

TREATMENT.

The treatment of fistula, like the treatment of any other condition, must be directed towards the removal of the cause. It may be divided into palliative and operative, and by far the greater part is operative. Some writers go so far as to doubt the value of palliative treatment in any case of fistula whatsoever, and others restrict it to occasional cases of the most trivial character. On the other hand, the cure of fistula "without the knife" is extolled in numerous advertisements, and in every city there are so-called medical men who have apparently made large fortunes by following the palliative treatment exclusively.

It seems to be the opinion of the majority of writers and operators that there is a certain small and definite class of cases in which the non-operative treatment may be advised and followed with a good prospect of success. But it must be admitted that even in cases which seem to fulfil all the indications for non-operative treatment, a certain percentage will remain uncured, or will relapse.

The non-operative methods are numerous, but all may be classed under one of the following heads:

NON-OPERATIVE.

- (1) Simple cleanliness.
- (2) Dilatation of external opening and packing with gauze.

(3) Application of caustics.

(4) Introduction of ligature, preferably elastic.

The cases to which any of these methods are applicable are those not attended with acute inflammation, or the presence of much pus; those which are not extensive; those which pursue a direct tract, without diverticula or branches; those which do not extend through the levator ani, and through what seems lately also, those which are grasping and scrambling fistulae, and show symptoms of being tubercular, though to the exclusion of this latter class some writers would disagree.

It is obvious that this classification limits to a marked degree the non-operative treatment; but beyond these limits the writer is convinced that palliative treatment at present should not be advised or undertaken. Exception, of course, is made of those rather rare cases in which on account of age or the general condition of the patient there is a definite contraindication to operation, or in which the patient refuses operation, and desires treatment, which is given with the distinct understanding that it will probably be insufficient.

CLEANLINESS.

It is a fact that certain superficial or marginal fistulae following fissures, or slight trauma, or very small abscesses, may heal, and heal permanently, if left to themselves and kept perfectly clean. Such cleanliness, however, must be persistent and scrupulous. Not only must the parts be washed at least once daily, and more often in warm weather, but they must be cleansed carefully after each movement of the bowels, and should be irrigated with some mild antiseptic or astringent, such as myrrh wash, or dilute liquor plumbi subacetatis. After the washing they must be made, and what is of great importance, maintained, perfectly dry. After wiping out the sinus, filling it with some inert powder, or with powdered boric acid, is at times of undoubted benefit. Such treatment is monotonous and necessarily of long duration. The cases are rare in which

it could be advised, and the patients who would carry it out are still rarer.

PACKING WITH GAUZE.

If packing with gauze is added to the cleansing described above, we have a method which will undoubtedly be sometimes followed by success. The method is common enough in the sinuses which follow operations in other parts of the body, and owes whatever efficiency it possesses to the cleansing which precedes it, and to the slight irritation to the sides of the sinus to which the packing gives rise. If carefully and conscientiously carried out, it compels whatever healing takes place to progress from the bottom of the sinus upward, and it prevents pocketing of the discharge; it also helps to prevent the introduction of dirt either from the rectum or externally. Gentle dilatation of the external orifice, with dressing forceps, or director, will facilitate the introduction of the gauze and the escape of the discharge. The frequency of the dressing varies with the amount of discharge, but will average approximately once in two days. Care must be taken not to pack too frequently or too solidly, as the former may mechanically interfere with healing, and the latter destroy the drainage. Iodoform gauze is unquestionably the best material, though baked gauze dusted with nosophen or aristol is also good.

CAUSTICS.

The application of caustics is a direct step towards removal of the cause of the fistula, and exciting union by adhesion or counter-irritation. All sorts of caustics have been recommended. Until late years nitric acid has been much used. It has been supplanted by ninety-five per cent. carbolic acid, which presents decided advantages over it—among others, that of being far less painful, and of being able to act efficiently without the formation of so deep a slough. The fistula should first be cleansed by the injection of peroxide of hydrogen in 15-30 volume strength, or of permanganate of potash, and dried. A wisp of absorbent cotton is tightly wrapped about the end of a fine probe or wire, previously moistened a little to help the cotton to adhere. The cotton is saturated with ninety-five per cent. carbolic, and introduced into the sinus to the bottom, or to the internal orifice, and is then rotated and rubbed against the sides. Care is taken to prevent the healthy skin in the neighborhood from being moistened with the acid. The writer has usually applied the acid once in three days, but it is probably better to apply it oftener. In two or three cases the progress at first was rapid and satisfactory, but later on the more superficial part of the sinus was more obstinate in healing. In one case it failed entirely, though it is only fair to say that this case had been operated on before, and has since been operated upon again, and is still not entirely healed. It was a good example of a case in which the palliative treatment should not be advised. It was undertaken as an experiment. Sinuses without greatly thickened walls are particularly favorable for this method of treatment.

The objections to this method are the possibility of using too great a quantity and producing too deep a slough. In obstinate cases it may be advantageously combined with a packing of gauze.

LIGATURE.

The use of some sort of ligature for the cure of

fistula has been recommended for centuries. Various materials have been used—linen setons, silk thread (sometimes moistened with caustic) and elastic ligatures. Whatever advantage this method of treatment may offer, it is certain that the elastic ligature possesses more of the qualities necessary for success than any of the others. Celsus has given an accurate description of the elastic ligature, and in recent years Dittel, of Vienna, and Allingham have brought it prominently before the medical world.

The elastic ligature is the means most commonly employed by those who advertise to cure without the knife. It seems to offer to the timid or busy patient a relief from his uncomfortable condition, without operation, pain or confinement to bed. It is needless to add, that if it had made good such promises, it would have revolutionized the treatment of fistula shortly after its introduction. The elastic ligature in the past, however, has not been without its dangers. One case in which it was used died with the symptoms of septicemia, and two others developed secondary abscesses, though they were purposely confined to bed in the hope of avoiding such complications. These cases occurred some years ago, however, and since then the elastic ligature has been employed at the Boston Dispensary and at both the hospitals in Boston with perfectly satisfactory results.

Dr. J. C. Stedman reports no less than a dozen cases satisfactorily treated and cured without unpleasant symptoms by elastic ligature.

Elastic ligatures are strands of pure india rubber from one-twenty-sixth to one-eighth of an inch in diameter. Round ligatures have been recommended, but the square rubber thread, used to make webbing, answers the purpose perfectly. English writers advocate the larger sizes, such as one-tenth of an inch in diameter, but most Americans prefer the small ligatures.

The cases adapted for its use are complete fistulæ, of not too great a depth, without diverticula and past the stage of acute inflammation. Here, again, English writers differ from Americans, in recommending its use in deep fistulæ, as an adjunct to the knife, making the final cut through the internal sphincter by the elastic ligature, after the superficial tissues have been divided by the knife. In this way, Allingham thinks he causes less injury to the sphincter, and is certain that he has less bleeding.

The operation consists of passing the ligature through the fistula, and fastening the ends tightly together. The only difficult part of the operation is the introduction of the ligature. For this purpose several needles and probes have been devised, and Allingham has invented a formal suture carrier on a handle, in which the end of the ligature is carried through a guarded eyelet. These instruments are unnecessary as a rule. The writer in one case passed the ligature easily, by simply bending down the tip of the ordinary silver probe over the end, then passing the probe and ligature through the fistula. The ligature is then put on the stretch, and either tied or, what is more easily done, caught between the edges of a split shot, which is then compressed by means of a strong pincers. It is at times advisable to dilate the sphincter gently, and it is often surprising to find how much the sphincter can be dilated without pain, if much care and a little time be devoted to the task; this is, of course, in the unetherized patient.

The ligature should be drawn as tight before fastening as its strength will allow, and it is best to test this before inserting it. If the fistula be a deep one, it is sometimes advisable to insert a small piece of gauze between the shot and the skin, to spread the pressure over a little greater area.

The ligature cuts out in from five to ten days, the fistula healing behind it, sometimes with remarkable rapidity; the tract at times is more than half healed before the ligature comes away. The pain varies a good deal; it may be very slight after the ligature is once introduced; at times the patient is compelled to use a quarter-grain morphine suppository and go to bed. The pain rarely lasts more than forty-eight hours. As a rule the patient may be on his feet the entire time.

If appropriate cases are chosen, a very large percentage will be followed by a perfectly satisfactory result. Allingham says he has not found the ligature as effective as he at first thought it would be; but he uses it in cases in which it could hardly be expected to be successful. Sometimes the ligature does not cut completely through and must be tightened, or the operation completed by the knife; and rarely the sinus refuses to heal after the ligature has cut through. The ligature should, of course, be soaked in strong corrosive before introduction.

The most serious objection to it is in choosing appropriate cases, for the simplest fistulæ are often found upon close investigation to possess unexpected diverticula.

OPERATIVE.

The choice in operative treatment is practically limited to two methods:

(1) Free incision, with granulation from the depth of the wound to the surface.

(2) Removal of the fistulous tract by dissection and uniting the wound by sutures to secure healing by first intention.

The second method may be modified in some cases by curetting instead of dissection.

These methods may be briefly described as Incision and Excision.

INCISION.

Treeves says of this operation: "To Percival Pott is due the credit of the present method of operating. It was a common practice in his time to excise the entire sinus, and it is still common to hear the uneducated classes speak of having a fistula 'cut out.'"

In preparation for any operation on fistulæ the patient's bowels should be moved by cathartics, preferably saline, on the day preceding the operation, and by enema on the morning of the operation, and, if possible, not more than two hours before ether is administered. The diet for a day or two preceding should be exclusively meat broths. The position of the patient on the table may be either that of dorsal lithotomy, or on the side on which the main opening of the fistula is situated, with the knees flexed sharply on the abdomen. Mechanical cleanliness must be encouraged by shaving, and antisepsis rather than asepsis sought for. So far as possible fistulæ should not be operated upon while acutely inflamed.

The sphincter must always be dilated fully, both to facilitate the discovery of the internal opening and to hasten healing. The fistula, or if there be more than one, the largest of the external openings, is then in-

vestigated with a fine probe, particular attention being directed towards the discovery of branches or blind pockets. The opening into the bowel is often difficult to find, and it is the rule rather than the exception to find that the tip of the probe can be made to travel up and down the rectal wall for some little distance without perforating it. The finger of the unemployed hand is now introduced into the anus and the orifice sought for. It is better not to force the tip of the probe through the mucous membrane if this can be avoided. It is advisable first to slit up the sinus from the outside a little at a time, with knife or scissors, in the hope of finding the inner opening as the operation progresses. The more carefully and thoroughly the incision is carried out, the better will be the chance of rapid and complete healing. Granulations or thickened sinus walls must be thoroughly removed by knife or curette, and small gas pockets or diverticula cleaned and scraped. The external sphincter may be freely incised without hesitation, but some care must be exercised in cutting the internal sphincter. It is desirable to leave part of its fibres intact, if this be possible; if not, it is absolutely necessary to cut through it at right angles, not obliquely, and it must never be incised in more than one place on pain of certain incontinence. Particular care must also be taken to avoid cutting the sphincters anteriorly in women, at the point where the fibres decussate, and are continued forward on the sides of the vagina.

The simplicity of the operation, in the average case, tends to make the operator less careful in its execution. As the result depends essentially upon its thoroughness, too much emphasis cannot be placed upon the necessity of discovering and laying open all branches and diverticula, however short they may be. This can only be done by examining carefully the floor and walls of the sinus progressively.

When the internal opening is well above the upper sphincter, three methods may be considered. The sphincter may be cleanly incised at right angles and left to granulate, or it may be incised and held together by a deep suture, or the elastic ligature may be introduced, as suggested by Allingham, at the bottom of an incision which reaches to the lower margin of the sphincter.

All bleeding should be stopped as far as possible by temporary packing. In superficial fistula it is rarely necessary to tie vessels if the snap forcep be allowed to remain on them for a few minutes. After determining that the floor and walls of the wound are thoroughly cleansed, it should be packed, not too snugly, with a thin layer of iodoform gauze, a pad and T-bandage applied. Some writers doubt the desirability of a suppository, but in an operation of any considerable extent it is better to insert it as a matter of precaution. A quarter-grain morphine suppository is sufficient.

Horse-shoe fistula should be thoroughly opened, but should be incised into the rectum in only one place, that opposite the larger opening if two exist. If there are multiple openings externally, paths of communication between them must be sought for, and can usually be found; they should then be opened from one to another and finally, in one place, into the rectum. In some cases the openings are so numerous, and the tracts so deep, that it is very advisable to do the operations at two sittings, attacking the deeper portions first and simply dilating the other orifices. Much ingenuity has

been exercised in determining the most advantageous methods of making the incisions between the various orifices, but cases vary so much that no general rule more than the above can be laid down.

The fistulae which are at once the most dangerous and most difficult, are those which perforate the levator ani muscle and penetrate the subperitoneal space in the pelvis. To open these thoroughly demands a very deep and often bloody incision, but unless opened thoroughly the operation is ineffectual, for the levator ani closes down and retains the discharge above, tending to the formation of the so-called hour-glass fistula. If the fistula is in the usual position, posterior to the anus, there is much less danger of wounding the peritoneum. If it is anterior, however, this possibility must be carefully borne in mind. The opening in the levator ani may be stretched with Bigelow's dilator advantageously, and the packing must be inserted to the bottom. Old, deep fistulae have been found to lead in all directions above the levator ani muscle and triangular ligament, and at times perforate bladder, the rectum or vagina.

As a rule, the dressing should be changed on the second day after the operation, and each day after that. Thorough cleansing is essential, and it is best to use peroxide of hydrogen, permanganate of potash or corrosive sublimate. The packing should be carefully introduced to the bottom of the wound, and in small quantity. Care should be taken not to allow pocketing of the discharge, nor to interfere with the granulation by too vigorous dressings. The bowels should not be moved before the fourth or fifth day, and an enema of warm sweet oil (four ounces) should be given and retained for one or two hours to soften the feces, before the soap-suds enema which is intended to clean out the rectum. The diet after, as before, should be exclusively animal broths, for at least four or five days, since these produce least fecal mass. The patient should lie preferably on the side opposite the fistula.

The after-treatment is, in a majority of cases, at least, as important as the operation. If good results are desired, the after-treatment must be carried out by a competent assistant who understands its indications. The patient should be kept either in bed or lying down while there is a granulating area of any considerable extent, as the motions of walking are not conducive to healing. In packing the wound, iodoform gauze has given the greatest satisfaction.

The duration of the granulating process varies extremely. It is rarely less than three weeks, except in the most superficial cases, and often reaches three months and more. It is especially long in the cases perforating the levator ani, and in cases originating from necrosis of the coccyx, or from the disintegration of pelvic glands. The character of the operation is so slight that the patient is often unprepared for the length of the monotonous convalescence. Of the 100 hospital cases recently operated in the Boston City Hospital the duration of the stay in the hospital averaged a little more than four weeks, the extremes being one and fifteen weeks. These cases were all discharged to the out-patient department, where they were under treatment at least two weeks on an average.

Whenever the internal sphincter is involved the patient must be expressly warned beforehand of the possibility of incontinence. Rarely is it true, of solid feces, but often of gas or liquids; and not unfrequently

this is a permanent condition. An insufficient sphincter, for which the owner is unprepared, is a memento of the operation which is not relished by either patient or surgeon, and is a poor exchange for a fistula which may have been but a slight annoyance.

EXCISION.

In order to avoid the slow granulation of a deep wound, American surgeons began to sew up certain cases of fistula, with the hope of shortening convalescence. In 1886 Dr. Smith published one of the earliest papers upon the subject. As surgery advances it is interesting to note that we are returning in a limited measure to the class of operation which is said to have been in vogue before the time of Percival Pott. The difference is, that at present fistulæ are not sewed up indiscriminately after operation, but the cases for excision are carefully chosen, and the value of cleanliness and antisepsis during and after the operation is fully recognized and appreciated.

Sinuses in various parts of the body have been excised and sutured for years, and there is no good reason why favorable cases in the ischio-rectal fossa should not be similarly treated. The essentials of the operation are that it shall be possible to remove the cause of the sinus, to convert it into a clean wound, and to keep it clean. If these conditions are obtained and maintained, the result will be the healing by first intention. The type of fistula therefore to which this method is applicable, is non-inflammatory fistulae, of moderate extent, with few branches; and also blind internal fistulæ of all varieties. In one case the writer has sutured a horse-shoe fistula with excellent result. The fibrous walls must be removed, preferably by dissection, sometimes with the curette. Granulations or pockets must be cleaned out with curette or Paquelin cautery, hemorrhage stopped, and the walls approximated by deep sutures. Silk is the material usually used. It is advisable to introduce each suture so that it encircles the wound and does not pass through its sides. For this purpose the so-called fish-hook needle has been invented. A strong needle with a sharp curve is essential, a Hagadorn preferably. The sutures vary in number according to the length of the fistula, and should be inserted at least as often as half-inch intervals. Sutures are removed in from three to six days; the dressing should be a wet corrosive pad, 1-3,000. The pain following the operation is apt to be greater than in simple incision. If the case is not progressing favorably, heat and redness increase, with the signs of retained pus; the stitches are removed alternately, and even in these cases a considerable amount of union is often gained. It is sometimes advisable, especially in old fistulæ, to insert an iodoform bougie into the bottom of the wound, and sew the sides together around it.

In superficial fistulæ it is almost invariably successful. In deeper cases it sometimes succeeds unexpectedly. It has never found much favor among English operators—most of them dismissing it lightly—and one (Cribbs) denouncing it as “opposed to every tradition of sound surgery.” Such an opinion is interesting as an indication of pathological conservatism, but is worthless otherwise. It would seem that the operation of excision for fistula will find a larger field in the future. Its obvious advantage is in the time gained in convalescence.

No matter what the method of treatment may be, a

certain percentage of cases which seem simple enough, will be found to be either obstinate in healing, or upon investigation to have recurred after a short period of apparent cure. In tracing cases operated during the past four months the writer has discovered such an instance. The man was discharged cured, after a dissection and suturing of a rather extensive sinus, which healed remarkably well. Two months afterwards, he presented a slight occasional discharge from an opening too small to be easily discovered, but which was so insignificant when compared to the condition before operation, that it would have been ignored by the patient.

In obstinate cases, second and third operations are sometimes necessary. By continued operation and care, however, almost any fistula may be cured, no less it be a symptom of an advanced general tuberculosis, or in a patient very much debilitated, or very old.

The question of advisability of operating upon fistulæ in patients suffering from pulmonary tuberculosis has been discussed at great length by almost every writer upon the subject. And yet the necessity for such extended discussion is not easily apparent. Of the 100 cases alluded to in the City Hospital, only three had symptoms which were considered of sufficient importance to be called phthisis complicating fistula. These three were operated and healed readily, and were discharged nearly well in one, two and four weeks respectively. More recently another case was admitted for operation in which the general condition was so bad that no operation was deemed advisable. The patient died of phthisis within three weeks. These cases show the indications for operating on fistula in phthisis, and they do not differ essentially from indications for any other operation in the same condition. Each case must be a law unto itself. If in the judgment of the surgeon the condition of the patient is good enough to withstand the operation, and if the benefit expected is greater than the discomfort attendant upon the operation, then the fistula should be operated. It is not a fact that such fistulæ refuse to heal. And when they are obstinate, the general condition, rather than the local etiology, is to blame. As a rule, a typical tubercular fistula is easily diagnosed by its large ragged openings—thin walls, sanious discharge and unhealthy appearance. In such operations it is well to substitute chloroform for ether; to get the patient into the sun and fresh air as soon as possible afterwards, to push the nourishment and to try and improve the general condition in every way. Gant, in speaking of this subject, says that five per cent. of all phthisical cases have fistula, and twelve per cent. of all fistulæ have phthisis. So far as the writer has been able to discover from a rather rapid examination of records, Gant's percentages are higher than the average for this part of the country.

While it is certainly true that occasional cases may be cured by cleanliness, caustic or simple packing, there are still only three methods which may be seriously considered in the treatment of fistula; and their importance and value rank in the order given: (1) incision and packing, (2) excision and suture, (3) elastic ligature. And in all of these methods, the after-treatment is at least as important as the operation itself.

THE Medico-Chirurgical College of Philadelphia has extended its course of study to four years.

CONSUMPTION NOT CONTAGIOUS.¹

BY CHARLES WINSLOW DULLES, M.D.,
Fellow of the College of Physicians of Philadelphia, Fellow of the
Academy of Surgery of Philadelphia, Surgeon to the Rush Hospital
for Consumption, etc.

IN the past eight or ten years the newspapers of most of our cities have contained numerous statements intended to prevent the spread of consumption by convincing the people that the disease is contagious. These statements have usually been made by too enthusiastic individuals in the profession, and sometimes by boards of health acting in their official capacity; but I do not know that any thoroughly conservative and dignified medical body has ever recommended the compulsory notification of consumption, although the matter has been repeatedly discussed by such bodies. The motives of those who wish to impress upon the community the idea of the contagiousness of consumption must not be questioned, but it is not improper to suggest that their theory may be somewhat strained in its application. I have for years been interested in this subject, partly from my connection with the Rush Hospital for Consumption, in Philadelphia, and partly from the interest every one feels in the matter; and I have collected some notes in regard to it that confirm the conviction founded on my own observation that it is improper to speak of consumption as a contagious disease, and my doubt of the propriety of considering it as to any marked extent infectious. I know that a number of interesting coincidences have been observed, showing the frequent occurrence of consumption in certain buildings; but I think a just estimate of the significance of these observations cannot be made at present, and that they deserve critical attention before they are regarded as conclusive; for it does not appear from what is recorded that the reporters and collectors of these cases have taken into consideration all the conditions that might tend to promote the development of consumption.

Almost all believers in the infectiousness of consumption have founded their arguments upon experiments that do not seem so conclusive when we reflect that the results of inoculation experiments conducted upon animals of a weak and unresisting constitution, and under circumstances most favorable to the destruction of their health and life, ought not to be compared without reserve to the dissimilar conditions of human beings who usually have the supposed *materies morbi* brought into contact with their unbroken cutaneous or mucous surfaces and, in the case of the lungs, only after sifting through the nasal passages.

A curious line of argument in support of the contagion theory, just now, is the claim that since the general promulgation of this theory there has been a decrease in the number of deaths from this disease. This diminution is, I think, real, although in some places it has been unquestionably exaggerated owing to a misapprehension of those who report it. For example, a certain elation has been felt by the New York Board of Health over a reduction of the mortality from consumption in that city. This elation was not at all remarkable, but it was corrected when attention was called to the fact that the figures used in recent years included rural sections of New York that did not come into the statistics of previous years, and to the fact that restrictive laws adopted by boards of health often put too great a strain upon the candor of

medical men, and lead them to report cases that they have reason to believe are cases of consumption under the head of some other disease, so that, for example, pneumonia, bronchitis, congestion of the lungs, and such titles are employed to cover up what is regarded as an uncomfortable fact.² I am informed also that in Philadelphia certain insurance societies refuse to pay their policies in case of death from consumption, and that as a consequence many cases of consumption are now reported under other titles. It is impossible, therefore, to speak very positively as to the exact rate of diminution of consumption; but the statistics of all civilized countries show that for the last twenty-five or more years there has been a pretty constant and fairly even diminution in the number of deaths from consumption, quite irrespective of any attempt at isolation of the cases or systematic disinfection of the sputa. Very recently Dr. Samuel W. Abbott has published an interesting letter³ accompanied by a diagram showing the comparatively even reduction of the mortality from consumption in Massachusetts in forty years, from 1853 to 1893, from forty-two to twenty-three per ten thousand of the population.

The zeal with which some medical men have pressed the idea that consumption is a contagious disease would naturally lead to a very exaggerated fear of the disorder, and in spite of the feeble and scattered and utterly inadequate attempts to limit its dispersion, it is comforting to observe that although countless millions of tubercle bacilli are spread abroad in public places and public conveyances, they do not produce the terrible results that one might naturally expect. It is furthermore comforting to know that it is hard to find in the world a single careful observer connected with an institution in which large numbers of consumptives are gathered who accepts the theory that consumption is in any proper sense of the term a contagious disease. I am not unaware of the instances, cited by a few writers, that point to a certain degree of communicability of consumption, or unfamiliar with papers like that of Dr. Kolb, of Kaiserlauten;⁴ but these may be offset by the observation of those who have been most in contact with large numbers of the disease. Dr. C. Theodore Williams, of the Brompton Hospital for Consumptives, in London, published an article in 1882, in which he gave a summary of the experience of this great hospital in the matter of the contagiousness of consumption. The figures indicate that only four persons in a number that I think may be fairly estimated at about five hundred, including resident medical officers, clinical assistants, matrons, superintendents, nurses, servants, gallery-maids, porters, secretaries, clerks, dispensers, chaplains, physicians and assistant physicians, had contracted the disease in the hospital.⁵ In 1883 Dr. Williams said, at a meeting of the Medical Society of London: "the evidence of the Brompton Hospital distinctly negatives any idea of its contagion in the ordinary sense of the word."⁶ At the same time, Dr. Drysdale said that he had for several years searched diligently for a case of transmission of the disease among his phthisical patients, but had failed to find one.⁷ Dr. Arthur Ransome, Professor of Public Health in Owens College, Manchester, published an in-

teresting article entitled "Consumptive Scare,"⁸ in which he refers to the alarming leaflets scattered broadcast in England (as they have been scattered in this country), and maintains that hospitals for consumption are not hot-beds of infection—as according to the contagion theory they should be—but that the universal testimony of physicians of these institutions is that "no such conveyance of the disease can be traced in any such institution." He furthermore says (and in this my own observations agree), "it would almost appear from the statistics brought forward, that their wards were the safest places in which susceptible persons could take up their abode." "I might say," he adds, "that my own personal experience after fifteen years at the Manchester Hospital for Consumption would be entirely favorable to this view."

At a meeting of the Cambridge Medical Society of England, some time ago,⁹ the communicability of phthisis was discussed, all the members having been asked by post for their experience. Out of thirty-eight replies, thirty-four were negative. At that time a statement was made by Mr. Lawrence Humphrey of the number of cases in which contagiousness could be suspected in the Brompton Hospital, as follows: Of four resident medical men (one for twenty-five years) none had any lung disease; of six matrons, none had consumption; of 150 resident clinical assistants, eight became consumptive, five died, but in only one was the disease developed during residence. Since 1867, of 101 nurses, only one died of phthisis, and that after leaving the hospital. Before 1867, six died, three of phthisis, but only one became ill and consumptive while resident, and she had a consumptive sister. Of 32 gallery-maids, since 1867, none developed phthisis while in the hospital. Of 20 house-porters, five died, but none of consumption.

At the Chest Hospital, Victoria Park, London, during the last fifteen years, of five resident medical officers, all were alive and well; of two matrons, none had consumption, and no clinical assistant was known to have developed lung disease at the hospital. One nurse out of 50 or 60 in the last few years became consumptive while at the hospital, and died after a year's illness.

Very recently Dr. Stubbart, speaking of the only hospital in New York for this class of patients, stated that there had not been a case of infection among the attendants.¹⁰ The experience at the Rush Hospital for Consumption, in Philadelphia, has been precisely the same.

In this connection I would refer to a paper by Kirchner,¹¹ who sought many times for tubercle bacilli in the dust of rooms occupied by a large number of consumptive patients, and found them only in one instance. The comparative innocuousness of dust which might fairly be considered the most dangerous conceivable is further indicated in an article on the "Dissemination of Tuberculosis by Infected Dust,"¹² in which Mr. Clifford Beale, Physician to the Victoria Park Hospital, for consumption, of London, says: "The theory has been so readily established that the tuberculous disease may be, and probably often is, conveyed into the receptive lungs, by means of inhaled

dust, and precautions against the possibility of such conveyance have been so widely advocated, that it would seem to be superfluous at the present time to offer any observations or criticisms which might tend to throw doubt upon so simple and satisfactory a demonstration; but, however satisfactory the facts may appear to be when looked at from the purely experimental point of view, it must be confessed that from the clinical standpoint they admit of considerable discussion. In order to satisfy the clinical mind it is necessary that evidence should be forthcoming to prove that those who are especially liable to the inhalation of infected dust should also be more prone to tuberculous disease than others who have not been so exposed. It is to the records of the hospitals for the treatment of phthisis that we should naturally turn for such evidence, and more especially to the records of the years anterior to the publication of Dr. Cornet's observations. It has, however, been abundantly proved that no such evidence is obtainable in this country. To take the experience of the chest hospitals at Victoria Park and at Brompton respectively, the figures collated and published by Dr. Andrew and Dr. Theodore Williams made it clear that no special liability to tuberculous disease could be demonstrated among the medical and nursing staffs of these hospitals during a period of twenty years. Quite recently Drs. Heron and Chaplin, in an article entitled "The Relation of Dust in Hospitals to Tuberculous Infection,"¹³ published the results of a series of experiments made upon susceptible animals by actual injection of dust taken from wards occupied almost exclusively by tuberculous persons, and have shown that such dust possessed but little infective power. From these observations it must be concluded that the dust of a consumption hospital is not especially dangerous to those who must of necessity inhale it, nor does it always set up tuberculous disease in susceptible animals when introduced by way of direct inoculation."

Mr. Beale then describes a study of the effect of breathing dust that might be assumed to be as thoroughly filled with the bacilli of tuberculosis and their spores as any dust could be. He inquired of some of the largest paper-mills in England and Scotland through the board of managers and medical officers in regard to the occurrence of tuberculous disease among persons employed in their mills, and especially in the sorting-rooms, at a time when hospitals for consumption did not practise disinfection. In the latter, as is well known, there is an enormous amount of dust suspended in the air, which is constantly breathed by persons at the age in which tuberculosis is most easily acquired. Although he found that no attempt was made to disinfect the rags, he could not find that there was any frequent occurrence of tuberculosis in the persons exposed to this presumptive danger. He found also that it was the opinion of persons connected with paper-mills that work in this particular atmosphere was not a cause of tuberculous disease. He found no case whatever of tuberculosis of the skin. Some replies which he quotes indicate that these were carefully prepared, with due appreciation of the importance of the subject. He admits that there is no positive evidence that in any of the places investigated there were rags infected with tuberculous matter. But the conclusion to which he has come is, that the facts he has gathered "go to support the view derived from the vital statistics of the consumptive hospitals that

presumably tuberculized dust is not a striking factor in the dissemination of tuberculous disease," and that "clinical observation abundantly shows that, in those very places where dust is most likely to be tuberculized, tuberculous disease does not appear to be disseminated." This interesting article confirms, as the author states, the deductions of Drs. Heron and Chaplin in their paper on the relation of dust in hospitals to tuberculous infection, in which they published the results of a series of experiments made upon susceptible animals by injection of dust taken from wards occupied almost exclusively by tuberculous persons, and have shown that such dust possesses but little infective power. From these observations it must be concluded that the dust of a consumption hospital is not especially dangerous to those who must of necessity inhale it, nor does it always set up tuberculous disease in susceptible animals when introduced by way of direct inoculation.

In the article alluded to, Drs. Heron and Chaplin¹⁴ described one hundred inoculation experiments made with dust from long uncleaned passages, shutters, pieces of furniture, and so forth, in the Brompton Hospital. In the entire series they produced tuberculosis by inoculation in guinea-pigs only twice. In reporting their own investigations they say it is very easy to attach too much importance to the results of research of this kind when it deals with only one hundred experiments, adding: "We, however, think we are justified in stating that the outcome of our work shows that in the wards and out-patient department of a hospital where a very moderate amount of care is taken to prevent the spread of infection from the expectoration of tuberculous persons, there is, within the limits of our observations, surprisingly little evidence of the escape of tuberculous bacilli to become a source of infection. Now, although it is true that the tuberculous bacillus probably retains its virulence at least as well as any other organism does when it is living a non-parasitic life, still it must be remembered that there exists no experimental proof to guide us where human beings are concerned, and, therefore, it is not known that it follows that because tuberculous bacilli will kill a guinea-pig or a rabbit, after the micro-organism has been lying in sputa which have been drying on a floor for, say, six weeks; we say it does not follow that, because the bacilli can do this, they could, therefore, in like circumstances, kill a man. It is known that the anthrax, which will surely kill a guinea-pig, is not by any means certain to kill an ox. In like manner there exists no proof that the tubercle bacillus which is taken from drying sputum, and which is surely fatal to the guinea-pig, will also kill a human being. It may be highly probable that it will do so in favorable circumstances, but that is the utmost that can be safely said within the limits of our present knowledge."

The observations of large hospitals for consumption is borne out by that of resorts for consumptives. It nowhere appears that the gathering of consumptives in certain places is an occasion of consumption among the original inhabitants of these places. Within a year it has been reported that there was a slight increase in the number of deaths from consumption in the Adirondacks in New York, but this is attributed by Dr. Trudeau, not to communication of the disease, but to deaths of persons who have come to the Adirondacks already consumptive and too late to be saved from death.

In German health-resorts, like that of Göbersdorf, it has been found that the death-rate diminished after the establishment of institutions for the treatment of consumption. There is a simple and natural explanation for this which does not compel us to go so far as to assert that the proximity of consumptives is *per se* an advantage. It is enough now to show that it is not *per se* a disadvantage. Very recently an interesting letter was published by Dr. Clinton Wagner, of New York,¹⁵ quoting one from Dr. S. E. Solly, of Colorado Springs, who sums up his experience and observation as a specialist by saying that "the dangers of contagion from a consumptive are so easily controlled that it is by no means necessary to separate consumptives from healthy persons. . . . At Colorado Springs the consumptives mingle with the other residents of the city on all occasions — at church service, theatre, concerts, and in the overheated and crowded rooms of private residences during social functions; they reside in the same hotels, boarding-houses, and private dwellings with those not afflicted with the disease, and no attempt at isolation has been made. Notwithstanding this apparent indifference on the part of the local authorities to the contagiousness of the disease, only twenty cases have originated in Colorado Springs in twenty years."

Dr. Solly also says, to disarm a possible objection to the obvious deduction from these facts: "In the poorer lodging-houses of the town there are many ill-ventilated rooms, inside or on the north side of the building, inhabited by consumptives and their families, where recklessness of expectoration and carelessness of ordinary cleanliness are marked features of their domestic *ménage*; yet cases of contagion do not average more than one a year."

Dr. Wagner says, from his own observation: "At Davos-Platz, in Switzerland, where I spent a winter a few years ago, a very large number of consumptives were staying. The hotels were crowded, and of the 1,500 strangers in the village, about 1,000 were consumptives. At the hotel at which I stayed there were about 120 guests, about 80 of whom were consumptives. At Davos, during the winter, the invalid's day for out-ing is limited to four and one-half hours; the remainder of the twenty-four hours is spent within doors. No one stood in dread of contracting the disease, and no cases occurred in which it was conveyed from person to person. No special precautions were taken by the physicians and local authorities to prevent contagion, other than good ventilation of the living- and bed-rooms. As in Colorado Springs, no cases of the disease originated at Davos."

At the last meeting of the American Climatological Association, Dr. Vincent Y. Bowditch, of Boston, earnestly deprecated the reckless and extravagant utterances regarding the contagiousness of pulmonary consumption made by medical men as well as laymen in a recent discussion in the daily press, and "showed that in well-regulated hospitals or sanatoria for consumptives contagion is almost unknown, or, at least, that with ordinary cleanliness and care as to the destruction of the sputa, the danger is reduced to a minimum."¹⁶

Notwithstanding these facts and others that would be mere repetitions of them from equally competent authorities, a few men still manage to disturb the pro-

¹⁴ Lancet, January 6, 1894, pp. 14-16.

¹⁵ Medical Record, February 7, 1896.

¹⁶ Journal of the American Medical Association, November, 1896, p. 1016.

fession and alarm the community from time to time with exaggerated statements on this subject, overlooking the fact that present observations and historical occurrences demonstrate that consumption is not contagious (in the ordinary sense of this term) and that extreme measures of isolation and disinfection are unnecessary and useless. Two hundred years ago, in places as remote as Ireland and Italy, consumption was regarded as contagious, and frantic attempts were made to limit its ravages. Naples set a custom that would hardly be emulated by our zealous American Boards of Health. In Naples and Rome it was customary to sacrifice the clothes and furniture used about the sick, and even to scrape the walls and tear down the woodwork of the chambers in which they had been sick.

The subject of the contagiousness of consumption and compulsory notification was thoroughly discussed by the College in January, 1894, and notwithstanding the labored and ingenious arguments of those devoted to the contagion theory, the conclusion of the College was that the evidence did not justify such measures as the contagionists thought to be essential to limit what they call the spread of the disease.

It is questionable, in view of what has been already stated, for one to say, without qualification, that consumption is an infectious disease; and, as I have stated in a paper read before the Medical Society of the State of Pennsylvania, May 18, 1897,¹⁷ those who have alarmed the world by expressing extreme views in regard to its infectiousness have committed a serious blunder, for, while observation justifies the belief that there is distinct danger that persons deprived of their liberty, with little opportunity for exercise, whose habits of life are changed, whose food may be insufficient, and who are herded with others suffering with consumption, may contract the disease from them (as shown by the statistics of convents and prisons), the malady can hardly be called infectious in a broad and general way. As Dr. Russell, of Glasgow, has said, "In the academic sense it is infectious; in the popular sense it is not," and those who wish to secure the observation of prudent rules of health would do well to avoid those extreme pronouncements which have been made in this country and in some others, and to rather copy the careful and discreet utterances of the French Society for the Prevention of Pulmonary Phthisis and other Forms of Tuberculosis, which, in a circular intended for general distribution, makes a statement that can be thoroughly endorsed by those who wish to do what they can to prevent the spread of this disease, namely:

"We know further that the consumptive is not in the least dangerous by contact or proximity; that it is never his body nor his breath which is hurtful; and that we can chat with him for hours, live with him for years, and even sleep in his room and give him the most constant care without running any serious risk, *provided we take certain precautions*, the chief of which is to collect his expectoration, and not delay the destruction of his sputum until it becomes dry and is disseminated as dust in the air."

Finally, although I have just used the word "spread" in connection with this disease, I think it is well to add that consumption is not a disease that is now spreading; on the contrary, in the time covered by most

accurate vital statistics of this country and Europe, it has diminished considerably in frequency. Some earnest advocates of restrictive measures have already claimed that the reductions observed within the past few years have been due to the attempts that have been made to restrict it by boards of health; but, fortunately, the community has a better reliance than this weak and inefficient one, and is encouraged by the knowledge that for many years there has been a comparatively steady decline in the proportion of cases of consumption. The disease is not spreading, as alarmists make the community to fear, but is actually contracting; and the hope may be entertained that, with the inculcation of reasonable and proper precautions, without spasmodic and violent measures, the ravages of consumption will become less and less, and it will soon cease to be the scourge and terror that it now is.

Clinical Department.

A CASE OF INTUBATION, AT THE AGE OF FOUR MONTHS AND TEN DAYS.¹

BY F. W. TAYLOR, M.D., CAMBRIDGE, MASS.

J. S., male; born August 11, 1896, always well till present sickness.

December 21, 1896. The child is large for his age, well developed and well nourished. The mother says that he has been fretful for several days; that yesterday about noon he began to be hoarse and to choke; and that he has been worse this morning. When seen at one P.M., the respiration was noisy, there was moderate laryngeal obstruction, both tonsils were enlarged, and covered with dense membrane. At 3.30 P.M., the rectal temperature was 102° F., pulse strong and very rapid, respiration labored, prostration slight, heart's action good; between 200 and 250 units of antitoxin (Massachusetts State Board's) injected. During the afternoon and evening dyspnea increased so as to threaten life, and at 11 P.M. intubation was done with partial relief. The child passed a sleepless and restless night, was unable to swallow, and much annoyed by mucus in the pharynx.

December 22d. The temperature rose during the day; and at 3 P.M. was 104.6°, pulse thready, respiration very rapid and obstructed by mucus. The tube was removed, and the respiration improved, as the patient could then swallow the mucus. Antitoxin (200 units) was injected. During the afternoon the child nursed several times, and had short naps.

December 23d. At 9 A.M. temperature was 101.2°, respirations 36. Slept four hours and a half last night. Dyspnea returned in the afternoon, became extreme in the evening, and at 9 P.M. intubation was again done.

December 24th. Patient breathes somewhat more easily, coughs frequently, nurses but little.

December 25th. Restless last night, coughed frequently, and was much disturbed by mucus in pharynx. At noon he coughed up the tube, slept comfortably from 12.20 to 12.50 P.M., and nursed well at 1 P.M.

December 26th. No membrane to be seen in throat. Patient slept two hours continuously in the

¹⁷ Comforting Facts about Consumption. Medical Age, June 10, 1897.

¹ Reported at the meeting of the Cambridge Medical Improvement Society, February 22, 1897.

morning and three hours in the afternoon, coughed when awake, nursed well.

December 28th. Hoarseness and cough continue.

January 8, 1897. Improvement has continued until within a few days. To-day, temperature 104° ; much cough; fine, moist râles generally distributed over chest.

January 17th. Convalescence established.

The tube which was used had been made to order several years ago. It is of the same diameter as the one usually used for a child one year old, but is one-fourth of an inch shorter. It was introduced with considerable difficulty. Dr. E. H. Stevens succeeding after several unsuccessful attempts, both by him and myself. As it was feared that extraction of the tube would be difficult, the string was left attached to it, the end being fastened to the cheek by adhesive plaster. The presence of the string in the pharynx probably accounts for the large amount of mucus, which was very troublesome as long as the tube was retained.

The only culture from the throat was taken January 5th, and was negative. The diagnosis of diphtheria is made practically certain, however, by the clinical appearances, and by the facts that during the week previous to this illness a sister had been kept at home because of sore throat, and that on the 2d of January another sister was taken sick, who on the 3d had abundant membrane in the throat, and on the 5th of January gave a culture containing Klebs-Löffler bacilli.

Enemata of peptonized milk and whiskey were given freely. The only medicines used were chloride of ammonium and syrup of ipecac, and these were administered irregularly.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. SECTION FOR OBSTETRICS AND DISEASES OF WOMEN.

C. H. HARE, M.D., SECRETARY.

REGULAR meeting, Wednesday, March 24, 1897.
Dr. M. Storer, chairman, *pro tem*.

GONORRHEA IN WOMEN.

DR. E. W. CUSHING presented the sociologic side:

I presume this is meant to involve questions not strictly medical; and I feel a little as Cicero may have felt when, in defending the poet Archeas, he asked his legal tribunal to bear with him if he handled the matter in a way not quite customary in the court. So in this reverend body I hope I shall be pardoned if in considering the sociologic aspects I sometimes drift away from the strictly medical side of the question. It is a very broad and important subject, one which within the last five or ten years has begun to be properly appreciated, but which I am afraid is not properly appreciated by the public, or even by the profession at large, at the present time—the immense importance of gonorrhea in women.

Gonorrhea is pre-eminently a disease of civilization, of crowding together. It is probably as old as the aggregation of humanity, and will last as long as humanity does. There are evident references to it in the

Mosaic Law—the segregation of men with a running from the flesh, the pains taken that all women should pass through the period of purification after menstrual discharges, which could have had its origin only in the fact which was observed then, as it is observed now, that immediately after or during the menstrual discharge infectious diseases were most apt to be communicated.

There are many ways in which gonorrhea is distributed in thickly-settled and in rich communities. One of the most important is prostitution, but that is by no means the only method, and in certain respects it is not the most common method. Prostitution has become a business involving a great deal of capital and skill, and commanding medical talent of a certain grade; and the consequence is that in well-regulated houses of prostitution the danger of infection is recognized, the pecuniary loss to the business is appreciated, and strong efforts are made, by the instruction of the unfortunate inmates in the care of their health, against the house getting a bad name. It is the great army of immoral persons outside the houses of prostitution, ignorant girls who have enough modesty not to take the means to secure themselves against infection, and not enough modesty to avoid the opportunity of infection, who are the great spreaders of this disease. In the last ten years I can remember only two cases of actual prostitutes coming from brothels who have required surgical operations, whereas the multitude of other young women thus affected who have passed under my observation has been something painful to contemplate. In Europe the great standing armies are a menace to the health of the community from this disease. I will merely quote a few lines from a paper recently read by Dr. Burr, in which, after referring to the various attempts to limit this disease in India, Holland and Japan, he says:

"The soldiers of the great standing armies of Europe carry this disease to their homes, on furlough or at the end of their term of service, and distribute the mischief to the innocent. Though not afflicted with the attendant evils of large standing armies in America, it is quite within bounds to say that one-half of our male population becomes infected with gonorrhea at some period of life. When we consider what a large percentage remains incurable (Noeggerath believed it to be 90 per cent.), we may know that a vast number of unfortunate wives must become infected also through no fault of their own."

If we, fortunately, have not great standing armies, we have other evils or methods of rapid distribution in the rapid growth of huge cities and the free communication between town and country, in the immense facility of commercial travel, in the growth of riches and luxury side by side with the spread of poverty and destitution, in the great armies of young women crowded in the cities, living alone and supporting themselves, living on insulcient wages, far removed from all the safeguards which in other times were thrown about women. That is something which has come up in the last ten or fifteen years to a great extent. The cities have increased, and the number of young women living and earning not enough to clothe and feed themselves is something appalling, and they are in contact with other women who have from their male friends clothes and all they wish for. The great aggregation of students in our large cities and great universities, as youths "just free from bar and bolt,"

has increased very much during the last generation. When I was in college 50 to 70 was considered an average number to graduate in a class. Now they number 200, 400, or even more, in the larger colleges, while the whole number of institutions of learning has increased immensely. Of course, out of such numbers of students there is a large proportion given to various forms of dissipation, and about all they really accept and remember of their alleged classical education is the maxim of Horace:

"Nec dulces amores
Sperne puer, neque tu choreas;
Donec virenti canities abest
Morsus. Nunc et campus et aræ,
Lenesque sub noctem susurri
Composita repetantur hora."

It has been argued that gonorrhea is a useful disease and an aid to morality, because it acts in the long run by obstructing the ducts of the epididymis of the too erotic of the men, and by destroying the function of the Fallopian tubes of the nymphs among the women, and thereby acts as an aid to the restraining influences of civilization, by permitting the propagation only of those who are able to restrain their sexual natures according to the requirements of the environment they live in, thereby furthering Herbert Spencer's idea that the future men and women will accommodate themselves to the limitations of civilization. That is probably a long way off. As far as we can see at present, the natural man has not changed very much from the earliest times. As for the ladies, we certainly have the very oldest bit of history of any kind extant to show that there were different kinds of women from the beginning. In the Talmud it is written that before Eve was created Adam had another wife — Lilith, blonde and emotional and sprightly — who would not live with Adam because he was slow and because he was a farmer, and who ran away with an interesting demon. There have been Liliths and Eves ever since. Few men know how women feel on these matters, and they will never tell, and it would be a libel on the sex to tell what women think and say about each other, but we have the authority of poets to think that women are not attracted by men to fall in love with them because they are good. You recognize that Goethe would have made a mistake if he had made Marguerite fall in love with a man who was pious and diligent and good to his mother; what took away her rest and made her heart heavy was:

"Sein hoher Gang, sein edler Gestalt,
Seines Mundes lacheln, seiner Augen Gewalt."

And so it will be forever.

Now, given the fact that gonorrhea is with us to stay, perhaps it would be all very well if it were limited so that it merely affected prostitutes, erotic young women and immoral young women. If it stopped there it would soon purify civilization. It has been said, if we had a jumping toothache fifteen minutes after every sin, there would soon be no more sins. Unhappily it does not stop here; wives are infected, babies are cursed with blindness, little girls become diseased.

A very large proportion of young men acquire gonorrhea. I think that is not subject to dispute. Just how large is the proportion I will not attempt to estimate. What proportion of men once affected with this disease become thoroughly free from it, and after how long a time, is a difficult thing to determine; but so much is known, that a very large proportion of

men who think they are cured are not cured, and infect their wives soon after marriage. Possibly the disease is aggravated by the fact that the natural excitement attending marriage puts an undue strain on the genital apparatus, and an undue congestion, and starts the latent germs into activity. At any rate, there are an immense number of innocent women infected. It is one of those things which has little influence on the people, because nothing is said about it, as the fatality of tuberculosis is not noticed, although if all the tuberculous could be gathered together we should see that it is worse than cholera or the plague. We had a great explosion the other day, and the city and the whole country were horrified. If I could bring together all the ruined lives, and the misery caused by gonorrhea, which I have seen in the last year, and put it together, there would be a worse shock and greater number of miserable victims from this one disease.

I have here very little to do with the pathology of this thing. I will merely run over the way in which it infects the women. There is first the localization in the genito-urinary tract, the glands of Bartholini, vulvitis; it passes into the cervix, into the uterus, into the tubes, makes salpingitis and the conditions which obtain as result of this gonorrhea. I see cases which have resisted treatment, which are brought for operation, and which do not get well under ordinary treatment. I have no doubt from what my friends tell me that a great many cases have it in a lighter way and do get well, and that the tubes may open and discharge, and the patient pass through a period of convalescence similar to that which occurs in epididymitis when the ducts are stopped up. Still, careful observations will have to be made on this subject. There have been great discussions in Germany lately; and Baum, formerly of Wuerzburg, brought up his observations on treatment. In spite of every kind of treatment, active or expectant, general or local, some 10 per cent. of his cases acquired pelvic disease of a serious nature.

The disease appears to vary in different places and in different communities. I am persuaded that in Philadelphia there is a more virulent form of the disease, with more tendency to suppuration, than here. There is something in the climate, in the race. In China and among the negroes they have a particularly virulent form; and I think what makes the Philadelphia gonorrheal infection so serious is the large amount of negro element in the city, bringing the worst forms of what the darkies call "lady fever" into cultivation, and thereby increasing the virulence of the whole lot. Also, they have had, until lately, no opportunity in the clinics or hospitals of Philadelphia to treat the disease.

What can we, as a profession, do in regard to gonorrhea? The first thing which reformists who wish to cure everything by law attempt is the regulation of prostitution; and that is the one thing which is bound to be a failure in this country. Evils of all kinds would immediately supervene if we tried to invent laws for the thorough regulation of prostitution. It has been tried again and again. Popes and emperors and kings and queens have attempted it, but without avail. Think of the evils which would arise if any attempt were made to regulate this thing by law! There would be a certain amount of false security which would only aggravate the disease. It is not possible to eradicate it in this way, even in houses of prostitu-

tion. I don't think any one who has followed the clinics in Paris and seen the style of doctor, or style of police supervisor, it breeds, would wish to have a similar state of affairs here. There would be demoralization of the police. Prostitution is a great business, with great capital involved, with unlimited opportunities; and from the slight uncovering of the thing in New York you can see what a stew the police would be in, in our government, if they had the system of arresting, confining and examining young women; the hideous chances of blackmail, arresting of innocent women and putting them with prostitutes. The mixing up of doctors with this is a dirty business, and it would drive the prostitutes into clandestine prostitution, which is the worst of any. Then comes the manifest injustice of punishing women and letting men go free. It would not be tolerated. It is not tolerated in England. To undertake any such system all over this country is, in my opinion, impossible, injudicious and unrighteous.

We cannot expect much from laws, for they rest upon public opinion, and until the public opinion is enlightened the laws are inoperative, and when that opinion is sufficiently enlightened the laws will follow of themselves. We have lived to see what a few years ago would have seemed impossible, the public opinion awakened to the question of tuberculosis, so that tuberculous meat and milk are condemned, and the food-supply of cities is cut off except as far as it can come from properly examined animals, and the milk unless it comes from cows that are exempt from tuberculosis. We have seen also an ordinance against spitting in the public cars. The office of the medical profession is to enlighten public opinion and not to propose laws.

Second, it has been proposed to make it incumbent on physicians to report to the board of health all cases of venereal disease under treatment. It is not the business of physicians to do the work of the police without remuneration, and it is against their first principles to go around declaring diseases which their patients do not wish declared. In certain cases where there is no moral stigma involved, as in diphtheria, and where actual danger overlies the community, the profession can be asked to do it, but they cannot be asked to carry out any such regulation as that in regard to venereal diseases.

Third, to make infection with venereal disease a ground for divorce and damages, even if latent at the time of marriage. That is a just provision, but at present it cannot be carried out; and it is a very delicate matter for the profession to take the initiative in saying anything about such things. Their position is to be dragged into the thing if necessary, but not to volunteer information.

Fourth, to make treatment of venereal diseases by druggists a misdemeanor. I don't think the public is ripe for that yet. Such legislation would be futile at present.

What can the profession do, and what is its duty in the matter? In the first place it can instruct itself so that it realizes the gravity of this thing, knows the means of scientific diagnosis, recognizes these diseases in women, really feels the seriousness of gonorrhea, as it has to treat it in young women and meet it in young wives. Next, it can act directly as an instructor of the community, naturally towards the patients themselves, indirectly through school-teachers and Christian asso-

ciations, by oversight over the police, the militia, firemen, colleges, schools, etc., and in that way the knowledge that gonorrhea is a great and threatening evil can be spread abroad among the community. Secondly, when the average young woman knows, and is instructed, that an unclean husband is going to be an imminent danger to her, she is going to refuse to marry such a man. Lastly, when the mother-in-law knows that the "catching cold" of her daughter immediately after marriage, that the "inflammation" is not catching cold, but an infection from a gonorrheal husband, that young man had better have a millstone hanged about his neck and be drowned in the sea. When the average young woman, her mother, sister, cousin and aunt, know that this disease is infectious, and that this operation is all the fault of the young husband, there will be a scorn arise for a dissolute young man such as is exercised against a dissolute young woman. What more can the profession do? They can take means to instruct themselves so thoroughly in the means of diagnosis which exist at present, that a young man before he marries may be able to get a clean bill of health and be able to know whether he will infect his wife or not. I see at least once a week all kinds of ruined hopes and blasted affections from this disease. It is a sad thing.

The profession can learn to do something to cure this disease in men. Unhappily, they cannot do much towards the cure of gonorrhea in women, but they can act by instructing and impressing on every one that it is a serious business. It used to be considered twenty or thirty years ago that gonorrhea in a man was a thing to be laughed about. All the popular misconceptions of to-day are the result of the erroneous teaching of the last generation, or the last but one of physicians. In the last twenty years we have lived down a host of things our grandfathers taught to their patients. If the profession takes gonorrhea seriously, the public will finally take it seriously. There is a great responsibility resting upon those who make scientific tests. It is no light thing to say a man is free from gonorrhea and may marry, unless a person can say it understandingly. It is no small thing for a man to say a patient has gonorrhea when he is not prepared to prove it; he may get himself into trouble. In these cases where gonorrhea affects women, and the relatives rise in wrath and want to know what is the cause of it, a man may get himself into trouble who knows too much. The easiest way out of it is to let them find out somewhere else by hypothetical questions the general facts of infection and the sources of pelvic inflammation and to settle for themselves the question of delinquency. Terrible to suggest as it may be, it is not always the husband who is the guilty party. The part of prudence and the desire to preserve the peace of families forbid us to say what we think, or even what we know.

"Est et fidei tuta silentio merces."

DR. WRIGHT: The pathology of gonorrhea is largely concerned with the gonococcus, its isolation and its occurrence in pathological processes. The gonococcus, which is the infecting organism in this disease, was discovered in 1879 by Neisser in the pus of gonorrhea and of gonorrheal conjunctivitis; and very soon after that he claimed to have discovered it in the exudate of gonorrheal rheumatism. It was early found the organism would not grow upon ordi-

nary culture media and the first successful attempt at its cultivation was made by Bumm, who used human blood serum as the culture medium. Since the work of Bumm to the present decade the cultivation of the organism made very little advances. In 1892 Wertheim gave us a fairly practical culture medium in the use of a mixture of sterile blood serum and agar-agar.

The bacteriological proof of the gonorrheal nature of various inflammatory processes has been a matter of slow development. The most important contribution to the subject was made by Wertheim in 1892. He put upon a definite scientific basis the teaching that pyosalpinx in the majority of cases was due to infection with the gonococcus. Wertheim showed that in 20 per cent. of all cases of pyosalpinx the gonococcus could be demonstrated by proper culture methods. In his paper he sums up the observations upon the occurrence of this organism in pyosalpinx. In 116 cases the gonococcus was observed in 32 while in 72 cases the material was sterile and in 12 various pus organisms were present. Since that time a number of investigations have been made on this subject and his observations have been confirmed. The interesting thing about the results of Wertheim is the fact that so many of these cases are sterile. That is to be explained on the ground that the gonococcus, produces its effects and then dies out. The mode of invasion of the gonococcus in pyosalpinx is evident. It affects the urethra first, next the cervix and the endometrium and then the Fallopian tubes. In recent years it has been shown that the organism can be the cause of endocarditis and of pleuritis. It has been repeatedly demonstrated in cultures from the joints in gonorrheal arthritis and some Vienna pathologists have claimed to cultivate it from cases of periostitis and of other suppurative conditions which were apparently secondary to gonorrhea.

The diagnosis of this condition from the bacteriological standpoint has been practised since the time of Neisser. It has long been regarded as a very simple matter to diagnose with bacteriological methods the presence of the gonococcus infection. Up to recent years the teaching was, that, if you made a cover-slide preparation of suspected pus, you were to make the diagnosis of gonorrheal infection if you found micrococci, of so-called double biscuit shape, arranged inside the pus-cells. No other organisms invade the pus-cells to that extent, nor did the other pus organisms appear in these flattened hemispheres with clear line of demarcation between them. This is not a sufficient ground for the identification of the gonococcus. If one examines pus from any abscess, one is liable to find appearances which are to all practically identical with the characteristic appearances of gonorrheal pus. Every pus coccus whatever, if examined carefully enough, will show this division into two hemispheres. Under the microscope the only reliable point of distinction between the gonococcus and the other pyogenic cocci, is the fact that the gonococcus is not stained when subjected to Gram's method of staining, while the other cocci are stained by this method. This fact shows that the gonococcus differs chemically from the other cocci. No diagnosis of gonococcus infection should be made until it has been proved that the suspected organism does decolorize with Gram.

The recognition of the presence of the gonococcus in the secretions of the genital tract in women, in cases where there is no special exudation of pus, is usually

very difficult and unsatisfactory owing to the frequent presence of large numbers of other bacteria.

DR. REYNOLDS: I do not know that there is very much to say on so trite a subject as the treatment of gonorrhea. I have been confronted with it a good many more times than I should have chosen. I am interested in what Dr. Wright said about the diagnosis. I had come to the conclusion from the clinical standpoint, that it was all very well to have the discharge under the microscope, but that it did not help one practically at all. You seldom get any positive reports from the pathologist on this point, and when you do it is what you do not believe from the clinical standpoint. It affects the vagina, upper genitalia and urinary organs. As regards the treatment of gonorrheal vaginitis I have tried a good many things, and have found nothing so satisfactory on the whole as the dry treatment in the vagina. I have settled down to the routine of having the vagina thoroughly opened in the Sims position, wiped out and cleaned with dry cotton, insufflated with aristol, then dry absorbent cotton and more aristol until filled up, having that done every other day.

As regards the treatment of gonorrheal endometritis, theoretically the thing to do is to curette it. I have no doubt there is a very transitory stage where the curette would do good. Practically I think it does not amount to much. You don't want to use the curette before the endometrium has been attacked. We used to hear a great deal about curetting during the acute stages of endometritis and salpingitis. I think everybody has fallen away more or less from that and personally of late I have dropped curetting these cases after the endometrium was really attacked. I think by the time you are sure you have an endometritis you have a salpingitis beginning, though perhaps you cannot recognize it. I am inclined to think I have seen cases where a salpingitis could have been avoided if the curette had not been used. When it comes to be a salpingitis, you can curette it, but I don't believe in doing it. You can also remove the tubes, and you can let the woman alone; and of the three I think the letting the woman alone is generally the greater triumph in gonorrheal salpingitis during the early stages. A good many come to operation in the end; a good many of them atrophy. The gonorrheal tubes seldom do very badly; and the indication for operation, it seems to me, rests a good deal on whether one or both tubes are involved, on the age and social condition and desires of the woman. It is a question in my mind, whether in case one tube seems to be involved, you improve the chance of saving the other tube by removing that one. If both tubes are involved, I think the majority of women are better off with atrophied tubes and ovaries than with no tubes and ovaries. It makes a good deal of difference to a woman mentally. There is a difference in the marital relation.

As regards the invasions of the urinary tract, the urethritis does not amount to much in women, as a rule. It is an acute affair that passes off. Cystitis is a little more important; it ordinarily subsides into a chronic sort of affair which is not very troublesome. The uretero-pyelitis which used to be regarded as an extremely rare affection has in the last year been shown to be pretty frequent though ordinarily a mild affair. It may in time break down a woman's health a good deal. I think the acute cystitis is treated best by putting the woman into the knee-chest position with as

empty a bladder as you can get, letting the bladder fill with air through a Kelly speculum and then filling it with a one-half-per-cent. solution of nitrate of silver, letting that stay a few minutes and then washing it out with salt solution. As you look at the bladder you will see two or three such applications as that clear up the bladder and leave only a few localized spots which you can treat with strong applications. There is the most marked difference between filling the bladder with a solution of nitrate of silver in that position, and washing out with nitrate solution in the ordinary way. Get it fully distended, and the solution will attack the whole surface, and there is a wholly different effect. I don't think you can hurry a pretero-pyelitis much when you get it. The case in the course of a year or two may improve a good deal under appropriate medicinal treatment, it may even get well. I think the preventing of these chronic ureteral affections is the most important indication for interfering with a gonorrheal cystitis.

DR. WASHBURN: I can only reiterate what has been said. I think the most important matter in the whole question is the matter of preventing the thing and not treating it after it gets started. The difficulty of treating the conditions is so great and unsatisfactory in their results that the matter comes down to the importance of preventing the attacks primarily, and that I am persuaded will not come until the medical profession as a whole take the step of impressing on the community at large the dangers of the infection and the gravity of the results that come from it. The habit has been of making light of the disease, saying it amounts to very little, may cause discomfort a few days or last a few weeks, but that that is all there is of it, whereas the gravity of the results from the conditions are being realized more and more by the medical profession, and should be by them made known to the community at large, so that the influence of the general public may be brought to the stage of realizing the necessity for stamping out the disease as much as possible.

DR. GARCEAU: I would like to call attention to certain cases of gonorrheal cystitis which in my experience have proved to be most difficult to cure by ordinary means. I refer to long-standing cases in which the inflammation has extended into the interstitial tissue of the bladder. Under these conditions irrigations and medicines exert but little action, because they do not come in contact with the seat of the disease. These cases are very apt to be complicated by extension of the inflammation up into the ureters and the pelves of the kidneys, and the irritation caused thereby aggravates the irritability of the bladder and gives rise to the constant urgent desire to micturate. Yet this extension upwards is not always a necessary sequel of cystitis, for in at least one case now under my care the inflammation was confined wholly to the bladder. She was a woman who had contracted gonorrhea about three years ago. This was followed by cystitis, and inflammation of the ovaries and tubes, necessitating the removal of the latter. Her bladder presented on cystoscopic examination the appearances usually seen in cystitis, but there was no ureteritis nor pyelitis, and care was taken to determine the presence or absence of these affections by physical examination and analysis of urine drawn by ureteral catheters from each ureter. She was finally treated by making an artificial vesico-vaginal fistula. The acute forms of

cystitis are very amenable to treatment provided the treatment is instituted at once. This is because the lesions are superficial and affect only the mucous membrane of the bladder. The so-called "subacute forms" are more difficult to treat; while the chronic forms are often very obstinate, even cystotomy with prolonged drainage sometimes fails to cure these patients; for when the artificial fistula is closed, they may be just as badly off as before.

DR. CUSHING: There is only one point I should like to add, and that is as to the question brought up by Dr. Reynolds, whether to operate on these cases of pus-tubes or leave them alone. I would point out some of the points which guide me in making this decision. The first point is as to whether there is any sign of suppuration, whether there is a chill or decided rise of temperature. It may be replied that that is owing to mixed infection, is not a purely gonorrheal affair. That is a mere academic distinction. The concrete case is a woman who is sick, and we want to know whether to operate or not. The fact that there is fever, especially with a chill, is a strong factor in deciding upon operation. The second point is whether the disease is accompanied by a great deal of pain. No one can judge exactly how much pain there is in another person, but my observation has been that women do not submit to operation merely because they are told to do so or on general principles. If it is left to them to decide whether the amount of pain demands operation, and that the dangers are fully explained, they will immediately divide it into two classes, the women who desire and must have operation because they are suffering, and the women who, as they are not suffering very much, will conclude they do not want operation; and that will be found always to correspond with the condition internally, the amount of inflammatory disease, amount of enlargement, and particularly the amount of adhesion and involvement of the intestine. The mere fact that there is a history of gonorrhea, a mass on one side which is not particularly painful, and does not show fever, is not an indication for operation in my judgment. The fact that the woman's usefulness is destroyed is sufficient to warrant operation. The fever, the pain and the involvement of the intestine as shown by difficulty of defecation, pain or obstruction, those are the main points, or the fact that an abscess is forming which requires evacuation of the pus.

DR. REYNOLDS: I quite agree with all that Dr. Cushing has said. I think the bad cases are rather the exception, but when they occur we have got to operate on them of course. I do not think that Dr. Garceau quoted me fairly, nor do I agree with the position that he takes. The quotations that are furnished us by Skeene and other authors are, I think, rather unfair, because the whole subject of the urinary diseases of women has been so revolutionized in the last two or three years, that things in print are mostly matters of the dark ages. I said, or meant to say, that I thought the cystitis was seldom a very troublesome or important affair except when complicated with uretero-pyelitis. It has been my experience, I think I can say without exception, since I have known the modern methods, that whenever a cystitis does not do reasonably well, the ureters, or one ureter and the corresponding pelvis of the kidney are affected, and I think in almost all cases, practically in all cases, you can with sufficient care and topical treatment get a bladder

well, and so get rid of the majority of the symptoms; then you have a long, slow time with the ureter. I think in the end most of these cases get well. If I had a case where the bladder did not get well, I should suspect the ureters. I see nowadays very few cases of simple cystitis that do not get well, and get well pretty promptly.

PATHOLOGICAL SPECIMENS.

DR. CUSHING: I have brought a tumor which I removed yesterday, which is interesting in that it is a tumor of the broad ligament without any pedicle. A woman of fifty-two had noticed something wrong three or four years, but only for a few months had known it was a tumor. In opening the abdomen no adhesions. Two gallons of fluid drawn off. The tumor had no pedicle, but dipped down into the pelvic cavity. The difficulties of removing a tumor of that kind are sometimes so great that I thought it would be interesting to explain the operation from the specimen. The Fallopian tube starting from the uterus is stretched across the tumor, and just below that the sigmoid flexure and lower part of the colon appear to be inserted directly into the tumor. It is not uncommon for errors to be made, and it is a very serious matter to separate the mesocolon by mistake from adhesions, owing to hemorrhage. I cut around the tumor through the peritoneum. This circle goes all the way around the tumor, and by a process of dissection the tumor was drawn out of the pelvis. It was under the peritoneum, and lay over the iliac vessels. I tied the ovarian artery. As the sac was separated from the uterus the latter was left entirely raw on one side. I thought it was best to remove the uterus and did so. In cutting across the uterus what appeared to be antero-posterior was really lateral as the pressure had flattened the uterus laterally. I had then a vast cavity down there, but I was able to bring the peritoneum over the bladder in apposition with the peritoneum running along just below the colon, leaving a glass drainage-tube in the bottom of the wound. The patient has recovered without accident. For comparison I have brought a tumor which I removed ten days ago; it is a regular multilocular tumor, in which you find daughter cysts, and expect to find a pedicle, whereas in the tumor first shown you must be prepared to find no pedicle.

I have also brought a gonorrheal pus-tube removed from a young woman married six months, and for the last three months an invalid. Mass in the pelvis, and getting larger, causing a good deal of pain, and I removed it. I have every reason to think it was gonorrheal. Her husband is a bar-tender. Recovery.

Sunday I did another case, which at first was supposed to be pus-tubes. A young woman, single, but with a lover, had a mass in the pelvis, high temperature, very ill. On opening the abdominal cavity, I soon got into the mass containing dark grumous blood; and letting this out and some large clots, I tried to bring up what I supposed to be a large tube. I found the upper surface of this was formed by the large intestine, of which one could see the appendices epiploicæ; and reaching down behind and separating, I could reach the ovary below. It was a difficult dissection, had to be done partly with the scissors to separate the bowel from the tube. The tube was removed. The other tube was diseased. That left a cavity the size of the fist. It was cleaned as far as possible, and Mikulicz's gauze dressing put in. Recovery.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, SEPTEMBER 2, 1897.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE INTERNATIONAL CONGRESS:
THE BRITISH MEDICAL ASSOCIATION.

THE Twelfth International Medical Congress held at Moscow is over, having occupied the week from August 19th to August 26th; and the Sixty-fifth Annual Meeting of the British Medical Association is now in progress at Montreal.

The Secretary-General announced the attendance of members at Moscow as 7,300, of whom nearly 4,000 were from Russia, 800 from Germany, 800 from Austria, 400 from France, 300 from Italy, 300 from England, 120 from the United States, 20 from Mexico, 10 from Japan, 4 from China, and the rest from various parts of Europe, South America and Asia. The most notable of the addresses seems to have been one by Professor Virchow on "The Continuity of Life," in which he harks back to the Cellular Pathology and suggests that in the cell will be found the key, if it ever is found, to unlock the mystery of the ages, and the united labors of the biologist and the pathologist will be the means of the discovery.

The United States was represented among the honorary presidents by Dr. Senn of Chicago, and Dr. Thayer of the Johns Hopkins.

The next Congress will be held at Paris in 1900 during the French Exhibition. Professor Launelougue, of Paris, has been appointed President of the Committee on Organization, and Professor Chauffard, Honorary Secretary-General. The French representatives were received with marked enthusiasm by the Russians at the Congress, though we see no mention of their being subjected to the demonstrative hugging on the part of the gentle sex which took so acute a form with the sailors accompanying President Faure as to be embarrassing even to those well-seasoned tars.

A telegraphic summary of the first two days of the Congress is given in the *New York Medical Record*. Our special correspondents will furnish presently their impressions of the meeting.

The meeting of the British Medical Association at Montreal has so far been favored with perfect weather. The opening ceremonies, preceded in the morning by a meeting of the Canadian Medical Association to discuss the subject of Interprovincial Registration, took place Tuesday afternoon at the Windsor Hall, when the President, Dr. Roddick, delivered his Address of Welcome. This was followed by receptions, and in the evening Prof. Charles Richet, the official delegate of the French Government, delivered an address. Wednesday morning the Sections, eleven in number, began their meetings. Thursday and Friday mornings were also to be devoted to the work of the Sections, the addresses being delivered in the afternoons. Wednesday afternoon Dr. Wm. Osler, a Canadian by birth and our fellow-citizen by adoption, delivered the Address in Medicine, which will be found on page 221 of this issue. Both this address and Dr. Da Costa's remarks before the Harvard Medical Alumni Association, dealing with kindred matters, are recommended to the attention of our readers. The Address in Surgery was to be delivered by Mitchell Banks, F.R.C.S., of Liverpool, on Thursday afternoon, and the Address in Public Medicine by Dr. Herman Biggs, of New York, on Friday afternoon.

The arrangements made by the committee in charge indicate that pleasure was to go hand-in-hand with profit and science, to be judiciously tempered by social relaxation and the enlarging influence of travel and excursions. There is even an international golf match. The railways in all directions, and even as far as Vancouver, have made liberal reductions to tempt those inclined to wander after the meeting.

Next week our special correspondents will give their impressions of the Montreal meeting.

MEDICAL NOTES.

THE NEW PRESIDENT OF THE BRITISH MEDICAL ASSOCIATION.—The British Medical Association will meet in Edinburgh in 1898, under the presidency of Prof. T. Grainger Stewart.

DR. MARTEN HONORED.—Dr. Marten, chief of Dr. Roux's laboratory of the Pasteur Institute, has been awarded an honorary gold medal by the French government for his work in epidemiology.

APPROPRIATION FOR THE PHILADELPHIA POLYCLINIC HOSPITAL.—An appropriation of \$25,000 has been granted by the State of Pennsylvania for the maintenance of the Philadelphia Polyclinic Hospital.

BERI-BERI AT THE RICHMOND ASYLUM.—The epidemic of beri-beri at Richmond Asylum, Dublin, is still on the increase, the number of cases now being in the vicinity of 200. Fortunately the type of the disease is mild and the mortality slight.

THE MEMORIAL HOSPITAL IN HONG KONG.—The erection of a hospital for women and children is part

of the permanent memorial in Hong Kong of Her Majesty's Record Reigu, and the foundation stone of the Victoria Hospital was duly laid on Tuesday, June 22d, by the Governor, Sir William Robinson, G.C.M.G.

PROFESSOR VIRCHOW HONORED BY FRENCH SAVANTS.—Professor Virchow has been elected a foreign associate of the French Académie des Sciences. There are six other foreign associates of the academy, three of whom are Englishmen.

INFLATED THE BABY.—A little boy of Beaver Falls, Pa., placed the tube of a bicycle pump in a baby's mouth and began pumping in air. The child's stomach swelled like a balloon and in a few minutes she became unconscious. The mother is reported to have arrived in time to save the child's life and probably "blew up" the little boy.

A NOBLE PAIR OF BROTHERS.—Prince Luigi, who has recently with conspicuous judgment and skill, led the first exploring party to successfully reach the summit of Mount St. Elias, and that without a single fatality, is a brother of the Count of Turin, whose exploit in maintaining the honor of the Italian army by puncturing the epidermis of Prince Henri of Orleans, was commented upon in our last issue. It would seem to the impartial observer that the prince had found a more really satisfactory method of employing his summer vacation than did his younger brother.

THE IMMEDIATE REDUCTION OF THE DEFORMITY IN POTT'S DISEASE.—On July 24th, at the Royal Southern Hospital, Liverpool, Mr. Robert Jones and Mr. A. H. Tubby demonstrated on a series of cases of Pott's disease the manipulations for immediate reduction of deformity. The deformities were reduced with considerable facility. The forced reduction of the deformity in caries of the spine has been advocated at various times, but it has always met with much opposition. Recently the practice has been revived by Dr. Calot, of Berek-sur-Mer, who had employed it in 37 cases when he wrote his paper, and claimed that the recovery was much accelerated.

DEATH OF A WHALE FROM A CURIOUS CAUSE.—A white whale was recently brought to the New York Aquarium from Canadian waters, and died soon after from edema of the lungs, due to a strange accident. As is well known, a whale is obliged to come to the surface every ten or twenty minutes in order to blow, and is provided with a blow-hole in which there is a valve which opens and closes as rapidly as the whale exhales impure and inhales pure air. An eel became lodged in this blow-hole and, despite the efforts of the whale to dislodge it, it held open the valve in such a manner that the water rushed in and filled the lungs, thus drowning the whale.

THE ANATOMY OF THE NOVELIST.—Our Gray is becoming pretty old, and the cover is getting loose. Some of the pages are torn and others are missing. We are in need of a new anatomy. This new anat-

omy should be in part original, and in a part compilation. The chapters that are compiled should be taken from the dissecting table. The chapters that are original should be taken from the works of the modern novelists of the romantic school. In a newly-published novel that we recently picked up at a book-stall we came upon the following graphic description of the result of a duel between the hero and the villain; "The hero fell at the first shot. The surgeon bent over him. 'Safe,' he whispered. 'The bullet has grazed his temple, but had it gone an eighth of an inch deeper it would have severed the femoral artery.'" — *Medical Era*.

NEW ENGLAND.

OVER ONE HUNDRED YEARS OLD.—Mrs. Pamela Stevens died at her home in Andover, Mass., August 25th. She was one hundred years old on July 31st last. She was born in Lawrence, and was of the family of Stevens who were numbered among the early settlers of Andover.

TYPHOID FEVER AND MILK.—Several cases of typhoid fever having been recently reported from East Boston, an investigation was begun by the Boston Board of Health, which resulted in the discovery that the cases were due to infected milk supplied by a dealer who had in his employ as a washer of cans a man who was ill with the disease. The man was, of course, discharged, and the premises and plant of the dealer disinfected. A general inspection of the milk supplied in groceries, soda-fountains and all places where milk is dispensed throughout the city, has been begun by the Board of Health, and the inspection includes, not only the milk, but the manner in which it is kept and cared for.

PORTLAND WANTS THE MAINE MEDICAL SCHOOL.—It is reported in the daily press that prominent business men and members of the medical fraternity of Portland are endeavoring to have the Maine Medical School, now located at Brunswick, in connection with Bowdoin College, moved to that city. Over \$100,000 has been pledged in Portland to erect suitable buildings for this school, and an attempt is being made by those interested to secure \$20,000 of the fund left by the late Joseph Walker to promote education in Portland. If this sum can be obtained, the Maine Medical School will certainly be moved, it is said, to that city. One difficulty in the way, so far as the Walker fund is concerned, seems to be the fact that the city of Portland has filed an application with the trustees of the fund for \$26,000 for a manual training school. It is understood that an effort will be made at the next city government meeting Monday night to have the city withdraw its application, and this will leave the track open for the medical school. A canvass of the board of aldermen shows that four favor the withdrawal of the city's claim for \$26,000, and favor the moving of the medical school to Portland, while three of the board oppose the withdrawal of the city's application.

Miscellany.

DEATH FROM COLLAPSE OF A FOLDING BED.

THE folding bed has several times proved its capabilities of doing serious injury by shutting its confiding victims up for the night in a most uncomfortable, not to say dangerous, manner, so that when they were extricated in the morning they were much the worse for their experience. It is doubtless true that the victims of most of these accidents have been the worse for liquor, and perhaps were not as active as they might have been in meeting the attack of the folding bed when it could be successfully dealt with and before it had them pinioned in its deathlike and inexorable grasp. The writer has known an injury to the knee of a serious and lasting character to be due to the tender caresses of a too affectionate folding bed, but never until the publication of a recent report in the daily press has he been cognizant of a fatal result from this accident. The report is as follows:

Chicago, Ill., August 25, 1897. Al Hankins, a widely-known sporting man, was killed to-day by the collapse of a folding bed at 3908 Cottage Grove Avenue. He had just entered the apartment and seated himself on the edge of the bed, when it unexpectedly closed. Hankins' neck was broken. Persons in the place rushed to his assistance, but they were too late. Death had resulted almost instantly.

Hankins, who is said to have conducted a gambling establishment at the number given, was the youngest of three brothers who were prominent in the early days of the Montana gold fever, and for several years conducted gambling-places in that State.

He had since been addicted to horse-racing, so that perhaps certain God-fearing people will consider that the folding bed was only the agent of the Almighty in cutting off the wicked in the midst of his sinful career. If he had not succumbed to the folding bed he might have survived only to be struck by lightning or destroyed in some other manner so impressive as to prove a lesson to all who might be tempted to indulge in similar evil practices.

HIGH MORTALITY AT BOMBAY.

THE rise in the mortality in Bombay, writes a correspondent of the *British Medical Journal*, is causing some anxiety, the total reaching to 130 to 140 daily. It is, however, probable that this excess is not due to plague, but to cholera and to the influx of famine-stricken people. Professor Hankin, who has been recalled to Bombay to finish his work on plague, is now working at the Municipal Laboratory there. A general meeting of medical men was held in Bombay, on July 21, 1897, to discuss the registration of deaths in Bombay, and to put the system on a sound basis. The meeting was convened at the instance of the Plague Committee, of which all the members were present. It was decided that the printed rules previously discussed and approved by the Bombay Medical Union should be submitted to a committee of three medical gentlemen, who should determine whether the Plague Committee should recommend that the rules be adopted and issued under the Epidemic Diseases Act. The meeting was also of the opinion that there was very little recrudescence of the plague, except sporadic cases, and that the present high mortality was not due to plague, but to cholera and diseases of the bowels. Scarcity of labor and the consequent poverty of the

people and their inability to obtain sufficient food, lead to emaciation and death, adding to the general mortality. The opinion held by most medical men in Bombay is that the disquieting increase in the mortality is due also in no small measure to the narrowed resources of many of the poor, consequent upon slackness of work and dearth of grain. Mill hands have no difficulty in finding work, but many of the coolies and laborers, who usually obtain employment at the docks and elsewhere, are less fortunate, owing to the continued slackness in trade, and there is a larger number of unemployed than usual. Meanwhile, the price of grain continues very high, and many families have to go on a very restricted supply of food. Vitality is consequently lowered, and wetting in the heavy monsoon rain often brings on diseases to which the people, if better fed, would not succumb.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, AUGUST 21, 1897.

Cities.	Estimated population.	Reported deaths in each.	Percentage of deaths from						
			Deaths under five years.	Infectious diseases.	Acute lung diseases.	Diarrheal diseases.	Typhoid fever.	Diphtheria and croup.

Deaths reported 2,850; under five years of age 747; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebro-spinal meningitis, diarrheal diseases, whooping cough, erysipelas, and fever) 741, consumption 258, acute lung diseases 138, diarrheal diseases 542, diphtheria and croup 78, typhoid fever 51, whooping-cough 33, scarlet fever 12, cerebro-spinal meningitis 11, malarial fever 8, measles 6.

From whooping-cough Philadelphia 14, New York and Brooklyn 9 each, Baltimore 7, Cleveland 3, St. Louis 2, Boston, Fall River and Lowell 1 each. From scarlet fever Philadelphia and Lynn 3 each, New York and Brooklyn 2 each, Cambridge and New Bedford 1 each. From cerebro-spinal meningitis New York 3, Lynn 2, St. Louis, Baltimore, Providence, Worcester, Springfield and Malden 1 each. From measles New York 5, Lowell 1. From malarial fever Nashville 5, Brooklyn 3.

In the thirty-three greater towns of England and Wales with an estimated population of 10,992,524, for the week ending August 14th, the death-rate was 29.5. Deaths reported 6,212,

diarrhea 2,038, measles 134, whooping-cough 70, diphtheria 54, scarlet fever 36, fever 36.

The death-rates ranged from 14.6 in Swansea to 43.0 in Birmingham; Bradford 27.7, Gateshead 26.3, Huddersfield 16.4, Hull 28.7, Leeds 35.4, Leicester 34.1, Liverpool 40.9, London 26.2, Manchester 38.3, Newcastle-on-Tyne 27.1, Nottingham 32.5, Salford 39.6, Sheffield 37.9.

METEOROLOGICAL RECORD

For the week ending August 21st, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 21, 1897, TO AUGUST 27, 1897.

Leave of absence for one month, to take effect about September 1, 1897, is hereby granted CAPTAIN W. F. CARTER, assistant surgeon, attending surgeon, Baltimore, Md.

Leave of absence for three months, with permission to go beyond sea, is granted MAJOR PETER J. A. CLEARY, surgeon, chief surgeon, Department of Texas, San Antonio, Tex.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING AUGUST 28, 1897.

W. M. WHEELER, assistant surgeon, detached from the "Marietta," and ordered to the "Wheeling," September 2d.

G. ROTHMAN, passed assistant surgeon, detached from the "Wheeling," and ordered to the "Marietta," September 2d.

RECENT DEATH.

DR. THOMAS JOSEPHUS HAYES died at Beverly, August 25th. He was born in Beverly, January 24, 1862. He was educated at Boston College and the Harvard Medical School, graduating June 24, 1887. Immediately after his graduation he began practice in Beverly. He was chairman of the Beverly Board of Health, a member of the staff of physicians of Beverly Hospital and a member of the Massachusetts Medical Society.

GENERAL REMARKS ON GASTRIC DYSPEPSIA.

BY ELBRIDGE G. CUTLER, M.D., BOSTON.

DISTURBANCES of the gastric digestion are perhaps among the most frequent of human ailments. When we consider the complicated processes of the gastric digestive act, the wonder is, not that there are so many disturbances but that from the work we expect the stomach to perform we are not many more of us dyspeptics.

1. ETIOLOGY OF THE DIGESTIVE DISTURBANCES.

Frequently disturbances of the gastric digestion are caused by pathological structural changes of the gastric walls, and by morbid forms, sizes and positions of the stomach. Improper food, bad habits in eating and drinking, irrational modes of life, and general disturbances of the most various kinds, are much more frequently causes of gastric disorders, however, than are diseases of the stomach.

(1) To begin with, how we eat, quite independently of the choice of food, often lies at the bottom of functional gastric disturbances. Faulty preparation of the food in the mouth by insufficient mastication and insalivation paves the way for future trouble. Business men, physicians, artisans and others whose time is limited, frequently take in great haste large quantities of food which they wash down with hot or cold fluids. The work which the teeth and salivary glands could have performed, if they had been given the time for it, is expected of the stomach. For a time this organ performs the exacting requirements made of it, but gradually it loses its power to do so and dyspepsia has its beginning.

(2) Another great fault, and one which very frequently gives rise to digestive disorders, is, that the stomach is not allowed sufficient time to completely digest one meal before another is taken on top of it. The secretory power of the gastric gland-cells is limited, and they also require a certain period of rest in which to prepare anew from the blood plasma the store given up and exhausted by the digestive process. If this rest needed for regeneration is not afforded them a condition of exhaustion ensues, in which their secretion of gastric juice does not reach the necessary requirements, either in quantity or quality. Moreover, the filling up again of a stomach not yet emptied leads to an over-distention of the gastric walls, which gradually may produce a relaxation of the latter unless an increased motility of the stomach pushes on the food more rapidly and earlier than common. In the latter case the intestine has imposed on it a labor which is often beyond its power of accomplishing if it must receive the chyme in an insufficiently prepared condition.

The excess of food over its needs is usually rejected without further trouble by infants, though not always. In the later years of childhood the motility of the stomach is so great, especially in active children, and in those always on the go and growing rapidly, that they can take great quantities of food at relatively short intervals without being disturbed by it. When we examine the stools of such a child we will frequently find that by no means all that has been eaten

has been digested, and that in some cases in which undigested food is passed with the feces, gastric and intestinal troubles also occur.

Vigorous, full-grown adults can make the stomach perform great work when they do severe labor and take much exercise. But if they continue to take in the same amount of food when the mode of life has become sedentary, or from other reasons the bodily exercise has been given up, very soon repletion of the whole body ensues, accompanied by dyspeptic troubles.

As age advances the capabilities of the stomach, as of the other organs, diminish; the need of new nutritive material is less, and the body is more easily satisfied. The digestion of the various meals requires more time than in younger years, and supplementary between-meals may be burdensome. Disturbances of the balance between bodily taking in through food and giving out through work manifest themselves very soon with age by disturbances of all kinds and in all organs, especially in those which perform the functions of digestion, assimilation and excretion. An aged person, especially, to keep in good health, requires the wisdom to recognize what is good for the body and what is bad for it, otherwise he is threatened with premature disease.

(3) The choice of food, the composition of it, and the size of the meal taken at one sitting, naturally play an important part in the history of the development of digestive disturbances. Of itself an article of diet may be easily digestible; taken in too great quantities, poorly prepared, or in improper combination with other food, it may nevertheless upset the stomach. Milk, for example, and milk preparations, except perhaps whipped cream, which in the process of whipping takes up from the air enormous numbers of bacterial exciters of fermentation and decomposition, are generally accounted easy of digestion. But how often do we meet persons, not to mention infants, who cannot bear milk in any form or preparation, and who sicken with dyspepsia when, in spite of their aversion founded on instinct and experience, we get them to take it. There are also people who cannot bear eggs, and others who have an idiosyncrasy against this or that article of food used in daily life. I will mention here lobsters, crabs, scallops, many fish and strawberries, which are highly esteemed by many people, yet in others give rise to urticaria with oftentimes very severe dyspeptic difficulties.

It is impossible to lay down general laws about the digestibility or otherwise of certain articles of food, for the digestibility of a food depends on the individual secretory and motor power of the stomach, which in the same individual is not always the same, but is subject to enormous changes. Merely to speak of the influence of surroundings, what does one not eat with impunity at a church fair, a Massachusetts Medical Society meeting, or a class reunion? Beaumont's table of digestibilities is interesting but can lay no claim to general application. Concerning digestibility, we may say the following in general: that food is, as a rule, digestible and acceptable, which, without disturbing the stomach, can be digested by the gastric juice, and in not too long a time can be passed into the intestines without burdening them.

(4) The process of digestion, especially its duration, is frequently protracted by the ingestion of too much or too cold fluid. As Fleiner² says, a drink of ice-cold

¹ Read before the Massachusetts Medical Society June 8, 1897, and recommended for publication by the Society.

² *Lehrbuch der Krankheiten der Verdauungsorgane*, p. 114, 1896.

beer can wholly stop the gastric peristalsis for a shorter or longer time and cause great discomfort or even dyspepsia of several days' duration. A bad custom is the drinking of too cold mineral water at meals, or one too rich in carbonic acid, — so-called table water. The carbonic acid which is latent in the cold, when it gets into the stomach and is warmed, is rapidly set free and overdistends the stomach. A part of the carbonic acid escapes with belching, and brings with it air swallowed, or gas formed in the stomach; another part, however, gets into the intestine, and causes unpleasant conditions of flatulence. Often, to be sure, but not always, the carbonic acid rouses the peristalsis of the intestine; at least, many people have a movement of the bowels soon after taking soda water or champagne.

Water-ices and ice-creams are refreshing substances, which are rather to be included among drinks than among foods. They usually arrive in the stomach in a fluid state but still so cold that not every stomach can bear them, especially when it is empty or when the body is in a heated state. Experience teaches us that the application of cold to the abdomen often rouses the peristalsis of the stomach and intestines and with this intention an icebag is sometimes applied. With a full and distended stomach, and cold champagne and ices usually come at the end of a large meal, taking such things may cause a more rapid emptying into the intestine. Nevertheless, an ice is frequently badly borne because it pushes food not yet sufficiently prepared from the stomach into the intestine and thereby causes harm, and because the milk and fruit of which it is composed are not protected by the freezing process from the action of bacteria, and are therefore often already in a condition of decomposition, which continues in the intestinal canal.

Children at meals usually take a very large quantity of water to wash down their food because their secretion of saliva seems to be insufficient for all their food, they also pass out much water by the lungs and skin; at least the more healthy ones and those who are constantly active do so. It is naturally difficult in a child to keep to the proper amount of liquid always, and it is very easy for the delicate organism of the child to be temporarily upset.

(5) Adults, especially men, frequently supply the needs of the body for water by means of alcoholic drinks. The strong alcoholic liquors are detrimental to the digestive processes in the stomach, and are directly injurious to the mucous membranes of the throat, esophagus, stomach and upper intestines where they are chiefly absorbed. This is especially true of the customary glass of brandy or similar liquors taken after dinner. The chronic catarrh of the throat and stomach of spirit drinkers is ample proof of this statement. Nevertheless, we cannot deny that certain gastric discomforts, which arise after taking food rich in fat, can be removed by taking a glass of liquor. It is well known that fat in the fluid condition of fat drops remains lying in the stomach a long time, and causes by its separated fat acids an unpleasant burning sensation. Physiologists teach us, Quinke for example, that a relatively large surface covered with a thin layer of fat can be very easily freed from the latter by alcohol. One drop of alcohol put on an oiled glass plate is sufficient to completely clear up the layer over a large surface and free the same from oil. It is possible that a similar process takes place in the stomach, though we cannot prove it; while on the other hand

it is a fact that alcohol causes a powerful flow of liquid into the stomach, which may have a cleansing and emptying action. We must not forget, however, that alcohol precipitates pepsin and thereby has a checking action on the gastric digestion. For this reason the pepsin wines which are in frequent use seem to be irrational, and are said by Dr. Pfaff, of the Pharmaceutical Laboratory of the Harvard Medical School, to be without exception wholly inactive.

Though we may strongly advise against the use of strong alcoholic drinks after meals, and the so-called stomach bitters before them, we cannot wholly condemn the use of milder alcoholic drinks, as for example light wines or beers. The taking by adults of a moderate quantity of wine or beer with dinner, better toward the end or after it, is not only harmless but frequently is of service. Fanatics on the alcohol question who in the place of wine or beer would have us drink coffee and tea, according to most experience, thereby prove more detrimental to the digestive, the circulatory and the nervous systems, than by allowing the mild alcoholic drinks. In many persons coffee, and still more tea, rouses the nervous and muscular apparatus of the stomach to such a degree that the chyme is driven too quickly and hence in an insufficiently prepared condition into the intestine and gives rise there to all kinds of dyspeptic disturbances, as great formation of gas, flatulence, peristaltic restlessness, increased peristalsis, diarrhea and later relaxation of the intestine. The cardiac muscle, like the gastric and intestinal canal, is unduly excited, and not infrequently we observe after taking tea a long-continued pulse-beat of one hundred and more.

(6) The misuse of spices and succedanea as a cause of dyspepsia should be mentioned. The moderate addition of condiments to food has become necessary to most people through custom, and one may well say that the processes of digestion are hastened by condiments, in that they stimulate the secretory and motor functions of the stomach and often of the intestine as well. Nevertheless, all condiments are irritants. In tardy and insufficient action, atony of the digestive organs, the use of these irritants may be proper under certain circumstances; but healthy organs scarcely need them and they are directly harmful to excitable individuals, not only to their digestive organs, but also to the entire system, and particularly the nervous system. The continuous stimulation of the gastric nerves by highly spiced food leads to overstimulation and gradually to blunting and weakening of these nerves. Highly-seasoned food, as of hotels and clubs, by stimulating the digestive organs to excessive activity, may be the starting-point of immoderate eating and drinking, which may in turn be followed by diseases of the most diverse kinds.

Most of the patented meat- and albumin-surrogates found in hospitals and private houses act as stimulants, like condiments, and without calling forth the agreeable sensation of satisfaction. Personally I use the pharmaceutical fluid, or solid substitutes for meats only exceptionally, when the products of the kitchen are not accessible. The use of medicines in diseases of the digestive organs demands great care also, for the number of useful and necessary medications is not very large.

(7) Behavior after eating. If now in the choice, preparation and eating of food we must follow the laws of health, so must we also pursue a certain

course after eating or we shall suffer troubles. According to a Latin proverb quoted by Fleiner, "*Post cœnam stabis aut mille passum meabis*," we should take a short walk after eating. An old German saying, cited by Schiile, *klinische Beiträge zur Physiologie des Magens*,³ is "*Fliehe den Schlaf nach dem Essen*." On the other hand, we see the householder pets go to sleep after being fed, if they are permitted to do so. A great desire for repose comes over most people after the chief meal of the day, which has its explanation in this, that the stomach requires so much blood for its functions that but relatively little is left over for those of the other organs. At all events, great headwork is well-nigh impossible after an abundant meal, and if such work is forced it is at the expense of the digestion, which becomes retarded. Also, great muscular exercise after meals is not well borne, as was definitely settled by experiments of Dr. Cohn,⁴ and we frequently find dyspepsia among people of every age, who must walk in a hurry a long distance after eating to get to their work, whether it be school, work-shop or counting-room. The emptying of the stomach in such persons is interfered with mechanically, and also the muscular exercise takes away a good portion of the blood from the stomach to supply the muscles, and a diminished portion is left to help secrete gastric juice. The stomach for this reason remains too long burdened with food, the gastric walls relax under the too protracted pressure of this load, and there follows as a result the atonic disturbances of digestion.

With physical rest after eating, on the other hand, the secretion of gastric juice and the motility of the stomach increases; and in a comfortable dorsal or right lateral decubitus, the stomach can best push on the fluids it has received, and the contents which have become liquefied, into the intestine. Here the fluids are very rapidly absorbed and may cause a very considerable increase in the blood-pressure. In corpulent people of apoplectic habit this rapid rise of blood-pressure is often very serious and may prove fatal. An apoplectic attack which comes on during sleep after a meal is not to be attributed to the sleep, but to this increased blood-pressure because of too much food and drink.

II. GASTRIC DISTURBANCES AS ACCOMPANIMENTS OF GENERAL DISEASES.

The stomach takes a more or less active part in the diseases and disturbances which affect the rest of the body. It shows this most in the diseased processes of the parts of the digestive tract, lying above and below it and in direct connection with it. Diseases of the neighboring organs, hepatic, splenic and tumors, abdominal tumors, collections of fluid in the peritoneum or pleura, may mechanically interfere with the performance of its motor functions by crowding it or displacing its ostia, or by causing changes of shape or position, and thereby call forth dyspeptic conditions. Other disturbances, local or general, draw the stomach into sympathy through the medium of the nervous system, or the blood. Among the changes of the blood the ones we know most about are chlorosis and anemia, and all considerable degrees of these disturbances are accompanied by dyspeptic conditions. Anemic dyspepsia, as Fleiner calls it, is one of the most frequent

of conditions affecting young girls and women, not sparing children and men even. It is very probable that chlorosis, like many other conditions of abnormal composition of the blood, arises from anomalies of nutrition and digestion; the anemic conditions, on the other hand, arise from losses of blood of all kinds. An especially frequent one is the profuse menorrhagia, which is seen in women after a single severe pregnancy, or after several pregnancies which have rapidly followed each other. It is also frequent in uterine misplacements and inflammations.

In order to understand how dyspeptic conditions may arise in poor-blooded people, it should be remembered that all glandular secretions come from the blood and are only formed out of it by the specific activity of the secreting epithelial cells. Claude Bernard's experiment on the submaxillary gland best demonstrates this fact. On irritation of the facial nerve at its root the vessels of the gland become dilated, the capillaries become so distended with increase of blood-pressure that the pulsation of the arteries is propagated even into the veins, and, according to Laudois, more than four times as much blood as is normally the case flows back out of the vein. The small store of nutritive material is naturally soon exhausted from a small amount of blood, and thus it happens that too little and too feeble gastric juice is secreted by the stomach of poor-blooded people. It is probable also that the same thing is the fact with the saliva and the intestinal juice. The dyspepsia of anemics depends in the first place on a secretory weakness of the stomach. But poor-blooded people have also weak muscles, and their insufficiently or abnormally nourished nerves have an increased or diminished irritability. The small, feeble, gastric secretion of such people therefore may be coupled with motor and nervous disturbances of all kinds. With the improvement of the composition and quantity of the blood, and the stopping of the sources of loss of the same, these forms of dyspepsia are cured.

In like manner, as in anemia, the functions of the stomach, especially the secretion of gastric juice, may be disturbed by the influence of cachectic conditions, cachectic dyspepsia; and of acute or chronic fever, febrile dyspepsia. Presumably in the dyspepsias of the latter class, toxic conditions, toxic dyspepsia, play a greater rôle than high temperature; at least the gastric disturbances considerably outlast the febrile period in, for example, infectious anginas and particularly diphtheria. Often weeks and months even pass after an attack of diphtheria before the stomach completely recovers.

There are no pathological appearances to be expected in these forms of dyspepsia mentioned except perhaps in the anemic ones, since they are chiefly functional disturbances without organic changes of the gastric wall.

III. SYMPTOMS OF DYSPERSIA.

Digestive disturbances usually accompany most of the gastric diseases dependent on pathological changes of structure. They also occur in the morbid shapes and positions of the stomach, and, as might be inferred by what has preceded, they appear as purely functional disturbances of great variety, affecting either the stomach alone or the whole organism as well. They give rise to troubles of a very subjective character and often of markedly individual type. Naturally a negative local or general examination is by no means suffi-

³ Berliner klin. Woch., 1895, Nr. 50.

⁴ L'Abeille Médicale, Nov. 19, 1888.

cient to refer the troubles experienced by a patient to purely functional disturbances, and to exclude an organic change, that is, a true disease of the stomach; for even the most severe diseases of the stomach, as ulcers and even cancers, may often run their course without any external appearances.

According to their origin and course we may divide dyspeptic conditions into the two groups, acute and chronic. Generally, but not always, the troubles which come from acute dyspepsia are more severe than those from the chronic form. Nevertheless, in the latter there are often transient exacerbations of the digestive disturbances and accompanying troubles which take on an acute character.

(1) Acute dyspepsia begins as indigestion, following a meal which does not set well, an error in diet, an excess in eating or in drinking, and shows itself as a general sense of discomfort and an unpleasant feeling of pressure and fulness in the gastric region. The food lies heavy on the stomach, as if it were not digested and passed on. Rapidly or gradually the discomfort increases, the stomach becomes distended, and nausea comes on accompanied by increased secretion of saliva. A feeling of burning in the stomach and behind the sternum increases the sense of thirst and causes repeated swallowing of saliva or the drinking of water, which allays the burning for a time. The patient temporarily feels relieved by eructations which may occur spontaneously or may follow a drink of water. But the trouble soon returns and increases in severity and may develop into intense crampy pains. Finally vomiting ensues with relief. Some people vomit with the greatest ease, especially children and adult males, while many women and girls can either not vomit at all or only with the greatest difficulty, the stomach being low down and forming a loop, and the esophagus being long and flattened. Where vomiting speedily follows or can be produced voluntarily either by suggestion or by thrusting the finger down the throat, the indigestion is soon over if the stomach can completely throw up its contents. Many people, not alone children, can immediately eat again after the stomach has been thus relieved of its burden, but they are more usually able to continue to drink liquid without great harm. A sound stomach endures much and will suffer long-continued abuse before it becomes disordered, and though it is usually considered to be a fortunate thing to possess a good stomach, it is an old observation that those who have to be careful of their digestion are the ones who live the longest.

The troubles last longer and often increase in intensity in people who either cannot vomit or can do so only after the course of some hours or the next day. In these cases, a greater or less considerable portion of the gastric contents, which is harmful through imperfect digestion and perhaps abnormal decomposition, gets into the intestine and causes great gaseous distention, colicky pain, increased peristalsis and diarrhea. It is noteworthy that where vomiting is relatively late the vomitus often consists chiefly of solid particles of food, which can be recognized, — the stomach in such cases having pushed forward into the intestine only the fluid drunk and the food which has become liquid. We see cases also where all the contents, both solid and fluid, have remained in the stomach with a considerable additional amount of fluid secreted by the gastric mucous membrane. These are especially the cases which are accompanied by great pain and seri-

ous general symptoms, as collapse and cramps; which complications are mostly due to reflex processes set up by the great distention of the stomach, or by the sudden relaxation of an over-distended gastric wall from the vomiting of large quantities.⁵ Fleiner⁶ considers that in the over-distended stomach there is a spastic or passive pyloric closure caused by mechanical pressure, more rarely that the downward traction of the overloaded stomach causes a kink in the duodenum. These conditions may be caused by the tight lacing of corsets, favored by dancing, sports, or other considerable muscular exercise.

(2) In chronic dyspepsia, the gastric symptoms are not so prominent as in acute dyspepsia; and what symptoms are present are mingled with general disturbances, which may be either the causes or results of the gastric dyspepsia. Intestinal disorders are also combined with chronic dyspepsia. As a result, the whole process of digestion, from the taking in of food to the time of fecal discharge, is associated with unpleasant sensations, sometimes more, sometimes less, according to the kind of food and drink taken. The sufferings which dyspeptics experience seem to increase when they are dwelt on even when those affected are not hypochondriacs, so that it is very difficult to provide for them in a household. Sometimes one kind of food, sometimes another, or its mode of preparation, is thought to be at fault. The result is that the diet list of most chronic dyspeptics gets to be smaller and smaller from omissions, and there follows a one-sided diet or insufficient taking of food and consequent loss of flesh. We sometimes see, however, well-nourished and even fat dyspeptics, who eat and drink too much and too good food and have contracted bad habits of all kinds to which their gastric troubles are attributable.

With the loss of weight, strength, and quantity of blood there is also a diminution of the gastric powers, the stomach becomes more sensitive and irritable, and digestive disturbances increase so that, at the first examination of such patients, one might well think there was a severe or even fatal disease. And yet frequently it only needs a proper diet and a rational arrangement of their mode of life to change, in the course of a few weeks or months, what was thought to be a severe condition of disease into one of perfect health.

The appetite in chronic dyspepsia is frequently, though not always, disturbed. It is oftener more from fear of the consequences of indulgence than from lack of appetite that too little is eaten. The tongue may be perfectly clean, though it is often coated, and many complain of a nasty taste in the mouth. There is very frequently chronic pharyngeal catarrh, especially in smokers and those who take liquors after eating to lessen their discomforts or strong wines to increase their strength. Hawking, retching and tendency to vomit in the morning, in such cases, is oftener attributable to the pharyngeal catarrh than to the gastric disturbances.

Complaints about the stomach in dyspeptics are tolerably uniform. Feeling of fulness, weight, uncomfortable pressure in the region of the stomach, especially in the pit of the stomach, come on during eating or soon after, and increase for a time and then

⁵ Fleiner *Archiv der Verdauungs Krankheiten*, 1895, Band I, s. 243.

⁶ *Lehrbuch der Krankheiten der Verdauungsorgane*, 1896, s. 151.

gradually diminish again. At the same time the pressure of the clothing is so burdensome that it must be loosened over the epigastrium; still a sense of stricture remains, there is frequently palpitation, intermittent or irregular pulse, anxiety sometimes coupled with feeling of heat in the head and coldness of the hands and feet. If there is belching, relief follows; and many dyspeptics try to bring on eructations as soon and as often as possible by contracting the diaphragm and abdominal muscles. Such eructations may occur during the entire duration of digestion; they often cease sometime after eating, and again they keep up even when the stomach is empty. Such patients usually say that this or that article of food keeps rising, and they claim to have this or that sense of taste with the eructations. It is exceptional, however, for dyspeptics without gastric dilatation, cancer, or ulcer to belch anything but an odorless gas. Frequently with the eructed gases, fluid, more rarely solid, gastric contents come up into the mouth, from which they are usually swallowed again or less frequently spit out.

Dyspeptics complain most of pyrosis or heartburn, that is, a burning sensation in the epigastrium, which may reach up behind the sternum to the throat or even to the mouth. It is generally considered that here we have to do with the rising of acid gastric contents and an increased secretion of acid in the stomach, but Einhorn⁷ says that the sensation can exist even without the presence of an acid, and McNaught has called attention to the fact that symptoms of pyrosis may be present with the normal quantity of acid. Ewald⁸ and Leube⁹ regard pyrosis as a kind of motor neurosis, especially a condition of irritation of the motor centres.

In simple dyspepsias, as a rule, vomiting does not occur if there are no accidental exacerbations of the old trouble through dietetic errors. The same is true of severe pain. On the other hand, most gastric dyspepsias are accompanied by intestinal disturbances which are often quite painful. Even during a meal or soon after it, many people with stomach trouble experience a distention of the intestines and a restless activity of the same, which are indicated by a rolling, clucking, quacking sound which may be heard even at a distance. Either the fluid and fermenting gastric contents get too soon into the intestine and are moved onward, or the energetic peristalsis which is roused in the stomach by being filled with food and drink, is imparted to the intestine. In many patients a desire to defecate comes on soon after eating, which may be several times repeated, and an abundance of stinking gas may also be passed at the same time. Such patients are often much troubled in thinking that it is the food just taken which has passed through them, which, of course, is not true. Wholesome advice in such cases always is, not to eat so fast and not to eat so much; for any one who regularly has two or three stools a day without at the same time emaciating, eats too much for his needs.

In sedentary people with a relaxed colon and abdomen a large and hasty meal may cause rapid accumulation of gas in the intestine at the hypochondria and epigastrium close under the stomach, giving rise to sharp, colicky pain, often wrongly attributed to the

stomach or to the liver or gall-bladder. The intestinal canal in such cases need not be diseased at all.

In contrast to these cases another series of dyspeptics complain of constipation. This arises in many instances from the fear of gastric discomfort, leading them to eat too little, and moreover to partake of a food which has little refuse matter, as meat and eggs. By the introduction of boiled farinaceous foods and vegetables into their dietary, the stools are frequently regulated without any further trouble.

Real diarrhea is found in dyspeptics, as a rule, only when the intestine, especially the colon, is affected together with the stomach.

IV. DIAGNOSIS AND APPLICATION OF THERAPEUTIC INDICATIONS.

In order to gain a knowledge of the processes which take place in the stomach, it is necessary in the first place, since external characteristic conditions in most dyspeptic cases are not to be found, to carefully compare the history of the patient with the known physiology of digestion and pathology. We should first try to draw diagnostic conclusions from the history of the patient which justify our therapeutic attempts before we use the stomach-tube and make analyses of the gastric contents. These latter should only be used when nothing more can be accomplished without them, and we are convinced of the necessity of their use. We are glad if we can help our patients without the need of the stomach-tube; on the other hand, we should never omit its use where we can thereby either avoid harm or may reasonably expect benefit to result.

It is especially the symptoms of eructation, formation of acid and pain in gastric dyspepsia, which are often very difficult to interpret.

In eructations, as a rule, only gas comes from the stomach, more rarely with the gas portions of the solid or fluid gastric contents come up also. The question now arises what kind of gas is this, and what is its source? By many it is too frequently regarded as the product of abnormal fermentation processes, carbonic acid, hydrogen, and so forth. The development of carbonic acid in the stomach occurs in alcoholic fermentation through yeast spores, and of carbonic acid and hydrogen in acetic fermentation, but almost always only in very severe gastric diseases accompanied by motor insufficiency. In such cases the development of an inflammable gas is no great rarity. In the ordinary functional dyspepsias gas fermentation is relatively rare. For this reason creosote, naphthol and other modern anti-ferments are seldom of any special good. Hoppe-Seyler says that the gas which is removed from the stomach by eructation is for the most part only atmospheric air. In many foods and drinks much air is held, and by this means gets into the stomach, where it remains a longer or shorter time. In mineral water, which is often irrationally taken with food, much air and carbonic acid is often contained, which thus gets into the gastro-intestinal tract. Moreover, many dyspeptics swallow considerable air with the saliva.

Increased production of acid in the stomach, and the sensation of heartburn dependent on it, may have a twofold cause: either increased secretion of hydrochloric acid, hydrochloric hyperacidity of the gastric juice, or increased formation of organic acids in the stomach. In the first case we have either increased irritability of the nerves of secretion, or gastric ulcer

and the gastric contents irritating the ends of the secretory nerves exposed in the base of the ulcer.

The increased formation of organic acids in the stomach depends on abnormal fermentation during gastric digestion. Perfectly healthy persons, who produce a good gastric juice, and whose gastric motility is sufficient, may at times be plagued by heartburn caused by organic acids. In such cases something eaten is at fault; the food has been too fat, as fried food, meat, or cereals, perhaps mayonnaise dressing, or food and drink undergoing the acid fermentation, whipped cream, sour cream, new beer or wine, and so forth. There is reason to believe that here the fat and fat acids remaining in the stomach give rise to the trouble, and, as already mentioned, a drink of spirits, as brandy or whiskey, will probably clear out the stomach the quickest, but it is to be very seldom employed for this purpose for obvious reasons. The acids which do not come from fats are soonest removed from the stomach by a glass of simple water, weak alkaline water, or a cup of weak tea.

In patients suffering from chronic dyspepsia a hyper-acidity of the gastric juice due to organic acids may develop even when there has been no dietetic error, as the result of atony, the stomach not emptying itself soon enough, and the food therefore remaining too long in the organ. Here the ferment organisms already present, or taken in with the food and saliva, have time to develop their activity. The fermentation process, moreover, is favored by a weak gastric juice, that is, one poor in free hydrochloric acid, as it does not sufficiently inhibit the pathological fermentations. If, however, there is good or increased gastric motility, such patients do not complain of heartburn but of intestinal discomfort; so that instead of a gastric trouble one thinks he has to deal with an intestinal difficulty.

How can we then in any given case with some probability determine, without chemical examination of the gastric juice, whether the pyrosis comes from hydrochloric or organic acids?

The burning caused by hydrochloric is much more severe than that caused by organic acid. It frequently increases to intense pain of a cramp-like or neuralgic character, which only ceases with the act of vomiting. Moreover, the burning, pain and vomiting often come on directly after eating, frequently even when the stomach is empty, and sometimes during the night. The taking of milk and egg sometimes lessens the trouble. There is often desire to take food at frequent intervals. Oftener patients with such symptoms suffer from constipation than from diarrhea or flatulence.

On the other hand, the heartburn caused by organic acids is much more frequent than from hydrochloric acid and, as a rule, appears sometime after a meal. It begins slowly and increases gradually without reaching great intensity or causing great pain. It is more troublesome than painful. Desire to take food is absent so long as pyrosis is present, but not because small amounts of food between meals really increase the heartburn. Occasionally a little sour-tasting gastric contents rises into the throat with eructations, but there is no real vomiting except exceptionally after great dietetic errors. On the other hand, there is frequently with the heartburn a marked gaseous distention of the intestine which may lead to severe colicky pain, if the intestinal peristalsis is slow, as so frequently happens. This latter condition then often gives rise to constipation, sometimes, however, there is tendency to diarrhea

or at least irregularity of the stools. Six or seven hours after the chief meal this sort of heartburn usually ceases and the feeling of hunger returns again. With an empty stomach in the night, for example, or early in the morning before food, heartburn caused by organic acid never occurs in contradistinction to that from excess of hydrochloric acid, unless the stomach is insufficient in motility.

External examination shows such stomachs as a rule to be relaxed, at least succussion sounds may be obtained in them several hours after the last meal.

Over-abundant secretion of hydrochloric acid is to be treated as in gastric ulcer and neuroses of secretion. A tumbler of cool water should be given early in the morning on an empty stomach. The diet should be restricted to milk, eggs, white meat, easily digested cereals, and vegetables and fruit. Usually more than the three stated meals are indicated. Symptomatically alkaline spring waters, lime-water and calcined magnesia can be used to neutralize the acid. Of the former, Fachinger, Bilin, Vichy and Vals are much used in Germany, a tumblerful of either of the first two, and a wineglass of either of the last two, a quarter of an hour before each ordinary meal. Alcoholic drinks should usually be interdicted and all condiments. Jaworski, Ewald and Hyem claim that sulphate of sodium has the property of reducing the rate of secretion of hydrochloric acid, and the latter author claims that the use of Carlsbad water may lead to the total disappearance of hydrochloric acid. He gives a small quantity of sulphate of sodium or of Vichy water every morning before breakfast. The chief thing is to reduce to a minimum the direct or indirect stimulation of the gastric mucous membrane. An objection which has been urged to the continued use of bi-carbonate of sodium is, that it becomes chloride of sodium in the stomach, which is a great excitant to the secretion of hydrochloric acid.

In severe cases the stomach should be systematically washed out before breakfast as well.

The treatment in the increased production of the organic acids is that of chronic gastric catarrh and gastric atony. As there is usually much secretion of mucus, this is to be removed either naturally by giving water to drink early in the morning, or artificially by washing it out by means of the stomach-tube. By the former or natural method the mucus is washed on into the intestine where, under certain circumstances, it can cause harm. By the latter or artificial means the mucus is directly discharged from the body. In all severe cases the artificial means is preferable to the natural because it is more thorough. The natural means is indicated in slight cases or in the subsequent treatment of severe ones already benefited and nearly cured by the washing process. Since mucus is not readily soluble in ordinary water, we usually add an alkali to it when we wash out with the stomach-tube. Experience teaches that a mixture of table salt and soda in the proportion of two to one is the best. The ordinary formula is chloride of sodium two parts, carbonate of sodium one part, of this a heaping teaspoonful is added to two or three quarts of water at 90.5° Fahr.

For drinking-waters there are many to choose from, for all the alkaline-saline and saline waters are proper to use. Among these are Carlsbad, Marienbad, Bilin, Saratoga Hawthorne Spring, Kissingen, Hamburg, Soden and Saratoga Congress. A diet of

milk, different cereals with milk and eggs, gruels and purées is best to begin with and is gradually increased.

Pain in the stomach when there is no decided structural change of the gastric wall, as hemorrhagic erosion, ulcer or carcinoma, present is most frequently caused by spastic contractions at the gastric ostia or by excessive distention of the stomach. In spasm of the cardia, true cardialgia, the location of the severest pain is behind the tip of the xyphoid cartilage in the pit of the stomach, and even higher up in the chest between the sternum and vertebrae, corresponding to the position of the esophagus. Since frequently no distinct cause can be found for this pain, and because it occurs suddenly and unexpectedly, and after a shorter or longer time disappears just as suddenly usually after a few eructations, it is for the most part regarded as nervous.

Nevertheless, such a cardialgia may very frequently be referred to purely mechanical causes. G. von Sweiten maintained the opinion, that in rapid overdistention of the stomach the orifices of the same were convulsively closed tight, and that such a closure could as well be the result as the cause of a painful gastric cramp. Furthermore, Fleiner¹⁰ calls attention to a bulging of the esophagus, which is frequently found partly above and partly below the diaphragm, which is bounded above and below by a narrowing, and which he calls a *vormagen* or *antrum cardiacum*. Gases, sometimes also acid gastric contents, rising from the stomach or coming from the esophagus, particles of food swallowed, caught in such an *antrum cardiacum*, become incarcerated and then give rise to troublesome pressure under the sternum, which usually disappears after one or two belchings.

Fleiner also says that the escape of gas through the mouth may be rendered difficult, in a purely mechanical way, without either spasm of the cardia or *antrum cardiacum*, by the powerful traction on the esophagus of a downward displaced and well-loaded stomach, or by a kink in the esophagus when the fundus is pushed up or displaced to one side.

Spasms of the pylorus, like spasm of the cardia, may be the result of undue distention of the stomach. It is, however, more often the cause of distention, because the sphincter of the pylorus can wholly close the opening and stop the exit of the gastric contents into the intestine. Also solid food may be temporarily held fast by it at the moment of its passage through the pylorus. Spasm of the pylorus is stronger than that of the cardia because the muscle is here in greater development.

Trousseau was the first to claim that half the so-called gastralgias were located in the intestine, namely, in the two flexures of the colon, more seldom in the transverse colon.

We have now seen that, with the exception of the pains dependent on great structural changes of the gastric wall, stomach pains and cramps come only from hindrance of the movements of the gastric contents either up or down. The important rule for the treatment of stomach and intestinal diseases to be deduced from this is that we should use opiates as seldom as possible, because morphia and opium paralyze the movements of the gastric and intestinal muscles for a long time. It is true that a subcutaneous injection of morphia acts rapidly and surely in a

gastric cramp, but it only gives temporary relief, it is not curative. The pain disappears quickly, the spasm relaxes, the muscle ceases to contract, but not alone where there was spastic contraction before but also in the whole stomach. The relaxed paralyzed gastric wall yields to the weight of the ingested contents and dilates, in which condition it is less able to drive out its contents than before. When the action of the opiate has ceased the stomach resumes its work under more unfavorable conditions than when it was interrupted. For this reason we must forbid all chronic dyspeptics the use of opiates if we wish to cure them, and restrict their employment to incurable and inoperable cases, as in carcinoma.

Almost all the medicaments used for gastric pain, especially cramp, have in view the facilitating of the emptying of the stomach into the intestine. And the household measures, except hot compresses to the abdomen, such as tea, black coffee, chamomile, peppermint, balm, valerian teas and the like, arouse peristalsis, open the pylorus and favor the emptying of the gastric contents into the intestine.

To find the relation or dependence of dyspeptic conditions on other local diseases or general disturbances we should not content ourselves with simply inspecting the tongue, examining the stomach, and perhaps the other abdominal organs, but we should make a complete examination of the patient all over. The lungs especially should be thoroughly examined, since very frequently the beginning of phthisis is concealed by gastric disturbances which spring to the fore. We should also never neglect to examine the urine at least for albumin and sugar. And sometimes the excretion of large amounts of uric acid will give points on many improper habits of diet and modes of life, or the finding of acetou or increased production of indican.

The blood should also be examined, especially as to its quantity of hemoglobin, with Fleischl's or other fit apparatus, once a week, and the patient should also be weighed. If by arranging the diet, changing the mode of life, ordering times of work and rest, resting after meals in anemic dyspepsias, we do not increase the hemoglobin beyond a certain limit, we must use mild preparations of iron, as ferratin or iron peptonates, in addition. A change to the mountains or seaside is often beneficial. If there be too great a loss of blood at the menstrual period, sometimes fluid extract of *hydrastis canadensis* in medium doses three times a day continuously, and of *viburnum prunifolium* twice a day, twenty to twenty-five drops, only during menstruation, prove of service. If these simple means do not suffice Czerny and also Fleiner advise the use of a tampon applied twenty to twenty-four hours after menstruation has begun, or in some cases directly at the beginning of the process in the ordinary manner. The tampon is allowed to remain in place twenty-four hours and is then removed, and after emptying the bladder and washing out the vagina it is reapplied a second time. Often a single tamponing suffices, though at times a third, fourth, or even fifth repetition may be needed. Of course this procedure has to be repeated at the next menstrual epoch. As the patient increases in strength the tendency to undue hemorrhage diminishes and finally ceases.

The oldest medical society in Russia is said to be the Physico-Medical, founded at Moscow in 1804.

TREATMENT OF CONSTIPATION.¹

BY FRANZ PFAFF, M.D., BOSTON.

THE best treatment in a given case of constipation will be the one by which the cause of the constipation can be removed. But the causes are very numerous. If a retro-flexed uterus is properly replaced, an intestinal stricture dilated or operated on, anemia cured or congestion of the lungs relieved, the accompanying constipation may be cured. Dozens and dozens of pathological conditions may cause constipation. It is not my intention to speak of all the different ways in which constipation has to be treated rationally according to its causation. I shall only deal with the treatment of cases which are generally classed under the head of the intestines, and in which peristalsis is believed to be insufficient.

In the treatment of these cases of atony of the intestines, it may be necessary to employ all the therapeutic agents available. Hygienic, physico-chemical, dietetic and medicinal measures, even suggestion and hypnosis, either alone or combined, may prove beneficial if regularity and perseverance in the treatment are maintained. Regular habits, out-door exercise, gymnastics, hydrotherapy, massage or electricity may alone prove sufficient in many cases of constipation.

But there still remains a vast number of cases of constipation which do not yield to such measures and in which we must promote peristalsis by other means. This may be done by diet or by medicinal agents. It is of these two factors I wish to speak very briefly. The dietetic treatment ought always be tried first, and if faithfully adhered to will often prove successful.

Of what should this dietetic treatment consist? The general rule is to increase in the daily meals vegetable matter, such as fresh green vegetables, fresh or dried fruits and the various grains. Further, to use the coarser breads, such as rye bread or graham bread, etc. The aim of this dietetic treatment is to introduce, with the green vegetables and fresh fruits, more water into the system, and at the same time, what is more important, to increase peristalsis through the stimulation of the intestine by the undigestible substances found in greater amount in vegetable material than in meats or fats.

There is absolutely no doubt that a great many cases of constipation improve under the treatment just outlined, and may even recover. But, on the other hand, there still remains many which are not benefited, but are often even made worse.

In spite of frequent failures, the principle of the treatment is not wrong, but only the application of it in special cases. The fault lies in making the increase in coarse vegetable diet without discrimination. A strong, fat, constipated patient whose digestive powers are normal may improve remarkably under such a diet, and his constipation be relieved for months and even cured. If, on the other hand, the same dietetic regime is prescribed in a case of chronic constipation, in a feeble patient with weak digestive powers, the result may be quite different. The constipation may become aggravated and the patient even lose strength and flesh. The reason for this is that the absorption of the real nutritive elements from our food stuffs is easier and more complete when they contain little undigestible matter than when they are loaded with such in-

soluble stuffs as cellulose, of which coarse vegetable material contains so much. And it is just this cellulose which is believed to act as the main stimulus to peristalsis.

The dietetic treatment of constipation is a much more complex problem than is generally thought and believed.

Any one who has examined the dry feces of cases of constipation microscopically and chemically will know how loaded they may be with vegetable waste products, and that the abundance rather than the lack of such undigestible matter should here be adduced as the cause of the constipation. The strength of the peristaltic movements are here entirely insufficient for expelling such an amount of waste products. If in such cases of constipation the quantity of undigestible matter of vegetable origin be reduced by the suitable choice of certain articles which have less cellulose, etc., but an equal amount of salts and carbo-hydrates, mucilage, pectins and other colloids soluble in water, the symptoms would very likely disappear, and the patient gain in weight. Recovery depends not only upon introducing vegetable matters into the intestine, but upon choosing such vegetables as are suitable to special cases.

Several different factors contribute to the good influence which the vegetable substances have on constipation. Of these the following are the more important:

(1) The transformation of carbo-hydrates into CO_2 and fatty acids such as acetic, butyric, etc. These fatty acids, it is true, are nearly entirely lost for nutritive purposes, but they stimulate peristalsis of the small intestine and so hurry the contents through more quickly, thus causing them to reach the large intestine in a more liquid form.

(2) Further, the presence of the different neutral salts and gums, mucilages, pectins and other colloids contained in vegetable material are most curative in an increased vegetable diet. The sugars are entirely absorbed in their passage through the intestine, but they are not so very easily absorbable from their watery solutions, and therefore keep the contents of the small intestines longer in their liquid form. The colloids, soluble in water, act in much the same way. The different neutral salts act in two ways. They also keep the intestinal contents in a more liquid form and act directly as stimulants to peristalsis.

Of the action of salts I shall speak more in detail when treating of medicinal agents.

The good influence attributed to the presence of water and undigestible material present in vegetable matter is of less importance. An excess of undigestible matter may even be hurtful.

Vegetable material containing a large percentage of tannic acid, such as blueberries, cocoa, chocolate, tea, have also to be avoided on account of the constipating action of this acid. The formation in the small intestines of fatty acids which act normally as stimulants to the peristalsis of the small intestines may of course be increased by adding fats to the diet. If the diet list is made up according to the principles just laid down, even a feeble constipated patient with weak digestive powers will be benefited, as he will have all the benefits of the vegetable diet without the unnecessary extra work of getting rid of too much undigestible material.

However, there still remain patients in whom, in

¹ Read, by invitation, before the Massachusetts Medical Society June 8, 1897, and recommended for publication by the Society.

spite of attention to general hygiene and diet, medicinal agents must be given to facilitate or promote peristalsis. These agents may be properly divided into two groups, the inorganic salts and the different organic compounds. The inorganic salts are subdivided, according to their action, into two classes, the chloride of sodium group and the sulphate of sodium group. To the chloride of sodium group belong all neutral salts, which are easily absorbed in the small intestine from their watery solutions. The beneficial effect which chloride of sodium and its allies have on constipation is in promoting absorption of food stuffs and peristalsis of the small intestine. These salt solutions are entirely absorbed in the small intestine and excreted with the urine. But during the passage through the small intestines these salt solutions stimulate absorption and peristalsis, and hurry along the contents, so that they reach the large intestines in a more liquid form.

Here then, the inspissation of the remnants will not be so complete as to hinder their expulsion.

To the sulphate of sodium group, on the other hand, belong all the salts difficult of absorption, such as sulphate of sodium, sulphate of magnesium and other magnesium salts, the phosphates and tartrates. All these salts are absorbed with difficulty in the intestinal tract, and are expelled for the most part with the feces, and not with the urine. In their passage through the intestinal tract, they prevent the absorption of water, and thus keep the intestinal contents, even in the large intestines, in a more liquid form, thus facilitating their expulsion.

The large group of organic compounds used in the treatment of constipation act, so far as we know, mainly by producing peristalsis of the large intestines. I will only mention rhubarb, senna, cascara sagrada, aloes, gutti, elaterium, colocynth, jalap and croton oil. It would take too long to describe the special merits of each of these; suffice it to say that some are powerful irritants, and have, therefore, to be used very cautiously; while others, like senna, cascara sagrada, have less irritant properties and may be given with impunity for long periods.

From this very short description of the main characteristics of different medicinal agents, their indications for use may, nevertheless, be deduced. But before doing this, I may be permitted to draw your attention to another medicinal agent, which, in helping normal absorption in the small intestines and promoting intestinal peristalsis, may be used with success in the treatment of some cases. If dried ox bile be given in suitable form and in sufficient quantity, constipation may be relieved even in very obstinate cases. When given in salol-coated pills to prevent absorption from the stomach and in large quantities, fifteen to thirty grains three times a day, before meals, the evacuation of the bowels may become entirely normal. Bile acts mainly on the contents of the small intestines, and the indications for its use are, therefore, limited. But we have seen that not enough stress has been given to the conditions of the contents of the small intestines in the treatment of constipation. In many cases, the accumulation of fecal matter in the large intestines is thought to be entirely due to the imperfect peristalsis of this organ, and the treatment is directed to it, often with varying results, whereas a modification of the contents of the small intestine would prove curative. In concluding the short list of medicinal agents employed in

the treatment of constipation, we must not omit atropine and physostigmine. The latter acts in stimulating the unstriated muscles of the intestine, and may, therefore, prove beneficial when those have to be strengthened. Atropine acts in the opposite way. It paralyzes undue contraction of the muscles of the intestine. If constipation be due to spasmodic contraction of the intestine, it may overcome this spasmodic contraction and allow the evacuation of feces, which could not be accomplished otherwise by the strongest aperient.

Morphia, which in general favors constipation, may also relieve spasmodic contraction. In speaking of spasmodic contraction of the intestines as a cause of constipation, especially in nervous persons, I will only add that Kussmaul and Fleiner, in 1893, described this form more in detail, and recommended large oil enemas as the best means of overcoming the spasmodic contraction and helping evacuation of the retained hard feces. These large oil enemas may also be used with great advantages in cases of simple atony, where retention of fecal matter is present in the large intestine.

Now to the indications for medicinal agents!

If we intend to promote absorption of food stuffs and peristalsis of the small intestine, we ought to use the substances belonging to the group of common salt. Mineral waters containing mainly this substance are Wiesbaden and Kissingen. To this group may be added bile. If we intend to promote peristalsis of the large intestine, the different organic aperients or laxatives have to be used. In case our intention is to keep the contents of the large intestine less solid, salts like sodium and magnesium sulphate and other salts difficult of absorption have to be employed. Very often it is best to give a combined medicinal treatment, that is to say, one which keeps the contents less solid and helps peristalsis along at the same time. In such a way we shall need to use less quantities of drugs to obtain the desired effect than if we used a medicine acting in only one direction.

But even in cases where we have to use medicine, the attention to diet must be paramount, and if carried out with perseverance will often permit of dropping medicinal treatment entirely, which must be the desideratum in the treatment of constipation.

ROUND SHOULDERS.¹

BY E. H. BRADFORD, M.D., BOSTON.

THE condition of round shoulders has been classed as a form of kyphosis, and this is undoubtedly a correct classification, but certain features deserve especial consideration. They are frequently seen in growing girls and boys, and occasionally in weak adults. The scapulæ drop forward, the posterior edges projecting behind. The shoulders seen from in front project with marked depression to the inner side, as if the clavicles were curved inward to an unusual degree. The neck is thrown forward, and the abdomen is protuberant, owing to an unusual hollowing in of the small of the back. The spine may be flexible, but in many instances, the upper part is stiff.

If the individual attempts to bring the uplifted arms to a vertical line, it will be seen that the hollowing of the back is increased by the individual, who thrusts

¹ Read before the American Orthopedic Association, Washington, June, 1897.

the abdomen forward, while stretching the arms straight above the head.

quite noticeable in many instances. Where the arms are raised, this is only done by an exaggerated hollowing in of the back.

FIG. 1. Waist, with shoulder-straps and side stocking-supporters attached.

FIG. 2. Skirts buttoned to waist.

FIG. 3. In raising the outstretched arms the back is arched forward in the lumbar region.

This condition can be more carefully examined, if the child is placed flat, face downwards upon a hard surface like a board, or table, with the arms at right angles with the trunk. If the hand of the examiner is placed upon the back between shoulders, and with the other hand, the elbow raised, it will be found that the arm can be pressed above the plane of the trunk. If, however, the arms are brought to the side of the head in the axis of the trunk, it will be found that in many instances they cannot be raised to the plane of the trunk. Frequently, the arms cannot be brought to the side of the head without raising the shoulders from the board, on which the patient is lying. In other words, the play in the shoulder-joint is limited in certain directions, and in some instances, the back play of the raised arm is seriously impaired. In some instances, this lack of free movement in certain directions will be found greater in one arm than in the other,

giving an inclination to twist on the upper part of the body. Usually, however, the defect is bilateral. This affection is not due to a contraction of the pectoral

FIG. 4. The effect of shoulder-straps upon the upper contour of the trapezius.

If a gymnastic class of growing children be watched while performing exercises, this will be found to be

FIG. 5. Front view, showing weakened trapezius.

muscles, which would manifest itself when the arms were at right angles with the trunk, but to a shortened condition of the ligaments, and possibly to an alteration in the joint surface in a certain direction.

In seeking a cause for this affection, some impediment to the upward movement of the arms suggests itself, and the effect of clothing needs to be examined.

Both for convenience and owing to an exaggerated fear of injury to the pelvis, as well as for the purpose of arranging the clothes tastefully, it is the custom in dressing children to throw the weight of the garments upon the shoulders, fastening the skirts, and in many instances stockings, to the waist. These waists are made of various shapes, but usually have a narrow shoulder-strap, which presses upon the upper portion of the trapezius, and upon the clavicles to the inner side of the head of the humerus. They also exert pressure, if pulled downward, upon the upper portion of the sternum. Where, as is usually the case, the skirts are buttoned to the front of this waist, a considerable drag is exerted, and in this way pressure falls upon the trapezius and the sternum, the head is thrown forward, the shoulders drop forward, and the chest is contracted. The amount of weight of the clothing is not inconsiderable, making the erect position less easily borne, the child naturally seeking the position of greatest comfort. Where stocking-sup-

porters are added, the downward drag may become more than would be supposed. Where a faulty position is assumed a greater part of the day, the soft tissues adapt themselves, and a faulty attitude becomes habitual, the ligaments adapting themselves to such a shape. It is not probable that any pressure upon clavicles is exerted, which would not cause a marked distortion, as these are particularly strong bones, though this may occur in rachitic children. Fortunately, however, in rachitic children, when rickets is most prevalent, the weight of the garments is not great. Somewhat the same effect may result from the use of suspenders or from the straps of an antero-posterior support in Pott's disease. Suspenders, fortunately, are not worn ordinarily until the figure assumes its shape. The prevention of this deformity is more important than the cure, which must necessarily involve a long-continued treatment, designed to stretch the ligaments and strengthen the muscles. It is important to bear in mind that the clothing should be so arranged that

The prevention of this deformity is more important than the cure, which must necessarily involve a long-continued treatment, designed to stretch the ligaments and strengthen the muscles. It is important to bear in mind that the clothing should be so arranged that

A RECORD OF THE TREATMENT OF FOUR CASES OF PULMONARY TUBERCULOSIS WITH KOCH'S NEW TUBERCULIN T. R.

[BY HENRY F. HEWES, M.D., BOSTON.]

I HAVE recently completed the treatment of four cases of pulmonary tuberculosis with Koch's tuberculin T. R.

The tuberculin used was manufactured by Lucius & Brüning. It is known commercially as "The New Tuberculin, Koch." In the administration of the tuberculin the plan outlined by Koch was followed.¹

The treatment was given on every second day. Each patient received an initial dose of one-five-hundredth of a milligramme, solid substance. At each treatment the dose of the preceding treatment was doubled, unless untoward symptoms occurred. The treatment was continued until the patient received a dose of 20 mg. without reaction. In the fourth case the treatment was pushed more rapidly. In the second case the doses were run up to 30 mg. The symptoms which were taken as signals for a halt in the treatment were, a rise of temperature of over .9° F. (one-half degree Centigrade), extreme malaise of the patient, or other evidence of marked constitutional disturbance. Where such symptoms occurred and appeared to be due to the treatment, the succeeding dose was omitted or made smaller than the rule called for, in accordance with the severity of the symptoms.

Where no untoward symptoms interfere the period of treatment should extend over 28 days. In the three cases which were treated by the rule the periods of treatment were 30 days, 40 days, 30 days, respectively. The fourth case was treated in 25 days. The total number of injections given was 64; the least number in a case 13, the greatest 21. The total amount of tuberculin given in the four cases (omitting the extra dose of 30 mg. in Case II) was 157.66 mg. The total cost of tuberculin for the four cases was \$49. The amount of tuberculin by cases was as follows: Case I, 39.02 mg.; Case II, 43.98 mg. (up to 20 mg.); Case III, 38.53 mg.; Case IV, 38.13 mg. The lowest cost by case was \$11.71, the highest \$13.47.

The tuberculin was given by injection into the muscular tissue. An ordinary hypodermic syringe was used. This was washed out with boiling water before using. For doses of 2 mg. solid substance and less the tuberculin was diluted with .6 per cent. salt solution, and, where necessary, preserved in 20 per cent. glycerine. The larger doses were given straight. The largest amount of fluid injected at one injection was one cubic centimetre. The first 20 mg. of tuberculin used was of the April manufacture, the next 20

¹ Deutsche med. Woch., 1897, No. 14.

mg. of the May manufacture. The remaining 117 mg. were of the July manufacture.

The temperature, pulse and respiration were taken in each case at least every second day, when the patient came for treatment, and as much oftener as possible. In one case the temperature was recorded three times daily. The other three patients worked throughout the treatment, and it was impossible to get as accurate a record as was desirable. All drugs were discontinued during treatment except cod-liver oil. The diagnosis was by bacillary finding in each case. The cases were in no sense picked cases. None of them were incipient in the strict sense of the term.

My idea in reporting the cases at this time is to give a record of the action of four cases under the tuberculin treatment. No conclusions as to the therapeutic results of the treatment can be drawn after so short an interval.

CASE I. Female, age 23, white, sewing-girl. Family history, good. Duration of symptoms, eight months.

October, 1896. Pleurisy of right chest. Acute attack lasted three weeks. Since that time a constant cough, at first hacking, of late loose, with profuse expectoration. For two months has been losing flesh and strength rapidly. Cough keeps her from sleep. Much shortness of breath with exertion.

Vomits on every morning with cough. No night-sweats. Weight last December 135 pounds.

Patient came to me May 1, 1897. Symptoms at that time were those described above.

Examination. Face thin, cheeks flushed. Respiration 28. Chest: both sides moved equally; at right apex fine explosive râles on inspiration; slightly increased respiratory and voice sounds; throughout right upper lobe scattered râles of a rattling, moist character. In the left chest, just below clavicle, an area (extending from the outer half of the clavicle to the third rib) of dulness; bronchial breathing and fine râles; moist and rattling râles at base. Heart normal. Abdomen normal. Trunk very thin. Throat: chronic follicular pharyngitis. Sputum consisted of leucocytes and epithelial cells. Tubercle bacilli present in large numbers. Urine contained no albumin. Weight 115 pounds. Temperature 99.8° F., pulse 100, respiration 28.

Patient was treated with inhalations of oil of peppermint and administration of cod-liver oil and oil of turpentine.

June 1st. Reported by letter. Feels much better. Cough much less frequent. No cough nights. No vomiting. Weight 117 pounds.

June 24th. Patient has taken no medicine since June 1st. She felt so much better that she thought she did not need it. Cough is getting worse again; growing weaker. Weight 114 pounds. Temperature 99.2° F.

June 28th. Examination of chest gave same results as on May 10th. Temperature at 11 A. M. 99° F.; at 4 P. M. 99.5° F. Sputum: tubercle bacilli present. At 4 P. M. $\frac{1}{60}$ mg. tuberculin T. R. injected to upper arm. Injections after this given at 1 P. M.

June 30th. Temperature 99° F. No malaise. T. R. $\frac{2}{30}$ mg.

July 2d. Temperature 99.2°. T. R. $\frac{1}{12}$ mg.

July 4th. Temperature 99.9°. Soreness and slight redness at point of injection. Much lassitude of a character which she has not experienced before. No T. R.

July 6th. Temperature 99.5°, pulse 98, respiration 28. Feels better; no soreness. T. R. $\frac{1}{100}$ mg.

July 8th. Temperature 99.5°. T. R. $\frac{1}{60}$ mg.

July 10th. Temperature 99.2°. T. R. $\frac{1}{25}$ mg.

July 12th. Temperature 99.4°. Slight nausea and general malaise last night at 7. No soreness of injection focus. T. R. $\frac{1}{12}$ mg.

July 14th. Temperature 99.1°. No malaise. T. R. $\frac{1}{1}$ mg.

July 16th. Temperature 99.2°, pulse 94, respiration 26. Examination of chest: Signs as before, but râles less marked. Weight 115 pounds. T. R. $\frac{1}{1}$ mg.

July 18th. Temperature 98°. T. R. $\frac{1}{1}$ mg.

July 20th. Temperature 98.8°. Slight nausea last night at 7. T. R. 1 mg., injected into thigh.

July 22d. Temperature 98.8°. No soreness or redness over area of injection. Weight 114 pounds. T. R. 2 mg.

July 24th. Temperature 98°. No malaise. Thinks that cough is much looser than at any time. Does not cough at all at night, but raises much sputum in day. Appetite good. Feels much better than at start of treatment, stronger and less easily tired. Some lameness for twenty-four hours after injection. T. R. 5 mg.

July 26th. Temperature 99°, pulse 94. Feels better than ever. Some redness about point of last injection still visible. Much soreness for twenty-four hours. Extreme lameness in walking. T. R. 10 mg.

July 27th. Temperature 98.7°, pulse 96, respiration 28. Very dull and tired yesterday afternoon. Much lameness after injection. No chill or collapse; no redness over injection. Feels all right to-day.

July 29th. Temperature 98.8°. Feels first rate. Examination of urine gives same results as before. Cough very loose. Sputum of a lighter green color, consistency not creamy as before, but tenacious. T. R. 20 mg.

August 1st. Temperature 99°. No malaise from last dose, but has felt well as usual ever since. Some lameness, but no redness over point of injection.

Examination of chest. Fine crackling râles at right apex. Fine râles and slight bronchial breathing at left apex. Râles at both bases. The râles everywhere are of a coarser, looser character than formerly. Weight 112 pounds.

Sputum: viscid, tenacious character; contains many cells as before. Tubercle bacilli present in fair number. The bacilli stain less brightly than before, many of them showing but a faint shell. I mention this difference in the staining of the bacilli simply as a fact, without intending to attach any significance to it.

Summary of Case. — Patient has felt better and stronger during and at the end of treatment than at any time during the month previous. Has worked throughout in a factory. Appetite excellent. Cough looser and less troublesome. No change of a definite character in local signs of lungs. Slight loss of weight. No reaction and very few untoward symptoms experienced as result of injections. Lameness for twenty-four hours after injection the principal discomfort. The treatment in this case could, in all probability, have been carried through in the 28 days without reaction.

CASE II. Male, white, age 48. Family history good.

Symptoms date from September, 1896. Cough, weakness, loss of flesh, all progressive up to February, 1897. At this time cough, with profuse green and yellow expectoration; drenching night-sweats; fever; vomiting; extreme emaciation; utter prostration; soreness of throat. Confined to bed from February to April. Took no medicines except stimulants. April 20th went to South Carolina. Improved rapidly in the South. Returned to Boston in June, at which time I first saw him.

June 6th. Symptoms: Constant cough, with much yellow sputum; constant soreness in throat, localized subjectively in region of left tonsil; weakness and shortness of breath. The weakness was much less than before his trip South. The weight, which had decreased 40 pounds from September to April, had regained 20 pounds. The night-sweats and stomach trouble had disappeared.

Examination. Very thin, skin sallow, cheeks slightly flushed, cervical glands enlarged. Respiration 26. Right chest moved much more than left. Over apex of left lung, just above the scapula, was an area of comparative dulness; bronchial respiration, and fine explosive râles at end of expiration. Back and front an area (corresponding to upper lobe of lung) of dulness; bronchial breathing and voice, but with no râles. At base of lung some moist râles, but no dulness or abnormal breathing. Right lung showed no signs of disease. Heart normal. Abdomen normal.

Much emaciation of trunk and limbs. The throat showed some chronic follicular pharyngitis, with anemia of membrane. Superficial ulceration of the left ventricular band of larynx. Ulceration of indolent appearance with much muco-purulent exudation.

Sputum was yellow and creamy; consisted of leucocytes and epithelial cells in large numbers. Tubercle bacilli present in large numbers. Temperature 100.8° F. at 2 P. M., pulse 100. Weight 121 pounds.

From June 6th to June 22d the patient was seen every third day, and the pulse, temperature and respiration recorded at these intervals. The pulse record varied between 90 and 100, the temperature between 100.8° F. and 99° F., the respiration from 24 to 28. The treatment during this time consisted of inhalation of oil of peppermint, menthol spray to larynx, and administration of cod-liver oil and nux vomica.

Urine examined twice. Contained slightest possible trace of albumin; specific gravity 1.028; few hyaline casts in sediment.

June 22d. Patient felt better than for months. Cough much less frequent; none nights. Pain in throat less. Appetite excellent. Bacilli present in sputum. Temperature 99° F., pulse 94, respiration 26. Weight 119 pounds. At 2 P. M. given injection of $\frac{1}{500}$ mg. tuberculin T. R. in upper arm. All other medicines discontinued.

June 23d. Temperature 98.8°. T. R. $\frac{1}{250}$ mg.

June 25th. Temperature 100°. No malaise. No dose owing to temperature.

June 26th. Temperature 100.4°. No malaise. T. R. $\frac{1}{500}$ mg.

June 28th. Temperature 99°. T. R. $\frac{1}{250}$ mg.

June 29th. Temperature 100.2°. No malaise. No dose.

June 30th. Temperature 99.8°, pulse 100, respiration 28. Weight 120 pounds. Throat appearances same. Lung signs unchanged. T. R. $\frac{1}{160}$ mg.

July 2d. Temperature 99°. T. R. $\frac{1}{100}$ mg. Much smarter after injection.

July 4th. Temperature 99.8°. T. R. $\frac{1}{75}$ mg.

July 6th. Temperature 99.8°. Lassitude and weakness. No T. R. given.

July 7th. Temperature 99.8°, pulse 100. Feels thoroughly ill.

July 8th. Temperature 100.2°. Does not feel well; lassitude; no appetite; pains in legs. It seems doubtful whether this off spell is due to treatment.

July 10th. Temperature 99°. Still feels listless. T. R. $\frac{1}{100}$ mg.

July 11th. Temperature 98.8°.

July 12th. Temperature 98°. Feels better. T. R. $\frac{1}{50}$ mg.

July 14th. Temperature 98.8°. T. R. $\frac{1}{40}$ mg. Severe pain with dose.

July 16th. Temperature 99.4°. T. R. $\frac{1}{30}$ mg.

July 19th. Temperature 99°. T. R. $\frac{1}{20}$ mg. Injection painful.

The doses were increased thus gradually, with the purpose of avoiding, if possible, the extreme malaise which was experienced from the 6th to the 12th. It is quite probable, however, that this malaise was due to the variation in his condition independent of the treatment, as it lasted one week after the tuberculin was discontinued.

July 21st. Temperature 100°. Seems better. Appetite good. Weight 117½ pounds. Pain in throat is worse. Examination of throat shows some spreading of ulceration to aretynoid; same indolent appearance.

From this date the ulceration was treated twice a week by application of 50-per cent. lactic acid. T. R. $\frac{1}{10}$ mg.

July 23d. Temperature 99.8°. T. R. $\frac{1}{5}$ mg.

July 25th. Temperature 100°. T. R. $\frac{1}{2}$ mg.

July 27th. Temperature 99.8°. T. R. 1 mg.

From this time on temperature taken three times a day. Injections now made in loins.

July 28th. Temperature 99.8°, 99°, 99.4°. Lassitude and pains in legs.

July 29th. Temperature 99°, 99°, 99.8°. Some sore-

ness at point of injection. Up to this time the soreness has never been troublesome, and has not lasted over twenty-four hours.

July 30th. Temperature 99°. T. R. 2 mg.

August 1st. Temperature has varied from 99.9°, six hours after injection, to 98° now. T. R. 4 mg.

August 3d. Temperature on 1st, at 6 P. M., 99.8°; on 2d, 99° at 7 A. M., 99.4° at night; now 99°. Much lassitude; pains in legs; feels very poorly. Much weaker and thinner than one week ago. Appetite poor. T. R. 6 mg. in back.

August 5th. Temperature from 100° to 99° since injection. Much lassitude. Weight 112 pounds. Pulse 90, respiration 26. Lung signs unchanged. Throat ulcerations cleaner, but still spreading a little. T. R. 10 mg. in loin.

August 7th. Temperature 98.8°, pulse 88. Feels very ill and weak. Some local soreness and slight redness for first time. T. R. 20 mg. in loin.

August 8th. Temperature 99.4° in morning, 99° at noon, 99.8° at night. Injection caused pain at point of insertion for half an hour; none since. Feels better than last week.

August 12th. Temperature has not been over 99.4° since injection; now 99.4°. No constitutional discomfort from dose. Appetite improving. Throat lesions holding their own; no spreading; no definite healing. Lung signs unchanged. Weight 112 pounds. Thinks cough much less frequent and entirely from throat. Character of sputum the same. Tubercle bacilli present in less number than before. Stain less brightly. Urine as before.

After the last three doses patient noted that the urine passed during twenty-four hours was full of urates. The throat examination and treatment in this case was made by Dr. J. L. Goodale, who has kindly given me his report.

Summary of Case.—It is very difficult to distinguish the changes in condition due to variations in the disease from the changes due to treatment in this case. The patient suffered from almost constant lassitude, loss of appetite and mental apathy during the second and third weeks of treatment. He certainly felt much worse than during the month before treatment. Symptoms unchanged. Physical signs unchanged. Loss of 10 pounds in weight. Much immediate discomfort from injections, especially the later ones. No definite reaction during treatment, but continual discomfort. Strength less than at start. The lassitude most marked, as a rule, about 6 P. M., four to five hours after a dose.

CASE III. Female, age thirty-eight, colored, domestic. Family history showed that mother died of phthisis. Patient first came to me September 21, 1896.

Duration of symptoms three years. Cough for three years, at the start dry and hacking, later loose with green expectoration. Except for cough has been very well until within six months. Since March, 1896, cough has been much worse; keeps her awake at night. Sputum occasionally blood-streaked. Steady loss of flesh and strength. Cold night-sweats. Dyspnea on exertion. Unable to work. Weight in December last 123 pounds.

Examination. Thin, exhausted appearance. Large glands in cervical region. Trunk very thin. Over both apices fine explosive râles at end of inspiration; no dullness or bronchial breathing. At left base behind, fine moist râles throughout lower lobe; no dullness. Heart normal. Sputum consists of leucocytes, epithelial cells and elastic fibres. Tubercle bacilli present in small number. Temperature 98°, pulse 90, respiration 24. Weight 103 pounds.

Treatment. Inhalations of oil of peppermint, administration of cod-liver oil and oil of peppermint.

During the winter patient improved very much. Cough became much less frequent, none at night. Sputum diminished in amount. Night-sweats disappeared. Strength returned. Returned to work. Weight in January 120 pounds.

January 10th. Examination. Very few râles at both apices; none elsewhere. No bacilli found in sputum. Peppermint inhalations discontinued.

February 20th. Cough worse again. Strength failing. Weight 108 pounds. Peppermint resumed.

May 20th. Weight 121 pounds. Feels much better again. Signs in chest as in January. Peppermint discontinued.

June 28th. Weakness and cough returned. Weight 113 pounds. No tubercle bacilli in sputum.

July 2d. Examination. Thin and exhausted appearance. Fine râles at both apices, of explosive character; no dulness. At bases of both lungs moist, bubbling râles in abundance. Weight 112½ pounds. Sputum characteristic of phthisis, but no tubercle bacilli found. Slight trace of albumin in the urine. Temperature 98° F., pulse 90, respiration 26. Given 5.0 mg. of tuberculin T. R. by injection into left upper arm; injection given at 9 A. M.

July 4th. Temperature 99°. No malaise. T. R. 2½ mg.

July 6th. Temperature 98°. T. R. 1½ mg.

July 8th. Temperature 98.6°. T. R. 1½ mg. No soreness.

July 9th. At 6 P. M. in night, taken with a severe rigor, followed by fever. Felt as if she were going to die. Much palpitation and dyspnea; extreme weakness; profuse sweating. To-day feels very weak and ill. Pain in head and in bones. Temperature 100° F., pulse 104, respiration 30.

Examination. No change of signs in lungs except that the râles are less abundant than formerly. Urine: slightest possible trace of albumin. Sediment as before. No redness or soreness at point of injection. Weight 108 pounds. No T. R.

July 10th. Temperature 99°. Feels better but still weak. No dose. The patient had an attack similar to this one in character and in consequences on June 17th, two weeks before the beginning of the tubercular treatment. In view of this fact it is difficult to fasten the blame for this attack of July 8th upon the tuberculin. However, I increased the doses more gradually for a time.

July 11th. Temperature 98°. Still weak. T. R. 1½ mg.

July 13th. Temperature 98.8. No malaise. Some soreness over point of last injection and a lump distinctly felt. T. R. 1½ mg.

July 15th. Temperature 98.7°. Much lassitude and weakness; worse at 4 P. M. Nausea and dizziness. T. R. 1½ mg.

July 17th. Temperature 98°. Better. T. R. 1½ mg. in thigh.

July 19th. Temperature 98°. T. R. 1½ mg.

July 21st. Temperature 98°. T. R. 1½ mg.

July 23d. Temperature 98°. Feels much better. T. R. 1 mg. in thigh.

July 25th. Temperature 98.7°. Pulse 90. Stronger and looks better. Weight 112 pounds. T. R. 2 mg. in thigh.

July 27th. Temperature 98°. Some pain throughout whole leg for three hours after injection. No tenderness now. Thinks cough is much lessened. Appetite very poor. Much general lassitude. T. R. 4½ mg. in loin.

July 29th. At 4 P. M. on 27th a sinking spell; palpitation and dyspnea followed by sweating and much weakness. Pains in limbs. No chill. Felt better but weak next morning. Now feels fairly well. Temperature 97°. No dose.

July 30th. Feels all right. Temperature 98°. Appetite poor. T. R. 10 mg.

August 1st. Temperature 98°. Felt dead and lifeless after dose of July 30th, but no collapse. Still weak. Lameness in leg for twenty-four hours after dose.

August 2d. Temperature 98°. Feels better. T. R. 20 mg.

August 3d. Temperature 99°. No reaction of any kind except general lassitude. Weight 109 pounds.

August 5th. Temperature 98°, pulse 90, respiration 24. On examination, signs of lungs unchanged. Looks thoroughly worn out. Thinks that cough is less frequent. Has noted that cough is more frequent on the afternoon

after treatment, and expectoration more profuse, especially with last four treatments. Thinks color of sputum has changed. Is weaker than at start, and suffers much from shortness of breath on exertion. Weight 107 pounds.

Sputum more tenacious and of clearer green color than formerly. No bacilli found.

Urine as before. Patient noted that for 24 hours after each of last two doses the urine was of high reddish color and cloudy. Examination showed that this was due to urates.

Summary of Case.—Patient has undoubtedly felt worse during treatment than at any time during eight months under observation. Has lost weight and strength. No appetite. Has complained of lassitude and weakness throughout. Physical signs unchanged. Patient experienced two distinct spells suggesting a reaction during treatment. That of July 9th did not appear to be due to treatment. That of July 29th did appear to result from treatment. Much lameness from injections in thigh.

CASE IV. Female, age thirty-four, colored, home, family history good.

Patient first came to me June 20th. History of a hacking cough for seven months. Two weeks before, sharp pain in the left chest, fever, chills, vomiting, extreme prostration. Constant cough, with profuse green expectoration, since. No night-sweats. No hemoptysis. Temperature 102°, pulse 120, respiration 36. Tubercle bacilli present in sputum.

Examination. Over left apex, extending to fourth interspace, an area of dulness, with bronchial respiration and voice sounds. Fine explosive and bubbling râles abundant. Few scattered râles at left base. Right lung normal. Heart normal.

After two weeks of treatment in bed patient returned on July 5th. Signs in lung unchanged. Patient still weak. Weight 99 pounds (weight in May was 125 pounds). Temperature 100° F., pulse 100, respiration 30. Tubercle bacilli numerous in sputum. Many cocci present.

July 6th. Given 5.0 mg. Tuberculin T. R. by injection in arm. Temperature 100° F. Injections at 10 A. M.

July 8th. Temperature 99°. No malaise. T. R. 2½ mg.

July 10th. Temperature 98.7°. Arm sore. T. R. 1½ mg.

July 12th. Temperature 99.4°. Cough troublesome. Feeling better than at start. T. R. 1½ mg.

July 14th. Temperature 99.5°. Felt ill all day yesterday; headache, lassitude, pain in limbs. T. R. 1½ mg.

July 17th. Temperature 99°. No malaise. Patient here went into the country for a week.

July 26th. Treatment resumed. Patient not very well in country. Signs in chest same. Weight 100 pounds. Temperature 99°. T. R. 1½ mg.

July 28th. On the night of the 26th was very chilly, and then very hot towards morning; weakness for half the day; but since then has felt better than usual. Temperature 98.8°, pulse 98°. T. R. 1½ mg.

July 30th. Temperature 98.8°. T. R. 3 mg.

August 1st. Temperature 98.8°. Soreness in leg at point of injection. A firm mass felt beneath skin, not tender. General feeling of lassitude for four hours after dose, then feels better than usual. T. R. 2 mg.

August 3d. Temperature 99.4°. Same experiences with dose as with others. Weight 102 pounds. T. R. 5 mg.

August 5th. Temperature 99.2°. Slight malaise of six hours. T. R. 10 mg.

August 7th. Temperature 99.2°. Eight hours after dose much lassitude. Chilly all evening, then very hot and sweat much. Felt fairly well next day, and now first rate. Extreme lameness all yesterday. T. R. 20 mg.

August 9th. Temperature 99.2°. Same lassitude and sense of impending illness in afternoon and evening. Physical signs unchanged. Râles perhaps less numerous. Feels stronger. Weight 99 pounds. Coughs much less. Urine as at start of treatment. Character of sputum the same. Tubercle bacilli present in the same number as

before. Stain with same brightness, but the contrast between the nodes and the spaces between is more marked than I have seen in any case. Noted passage of high-colored, cloudy urine after last two doses.

Summary of Case.—Patient felt better on the average during treatment than during the month before. Feels much stronger. Has gained weight. Showed a marked susceptibility to the tuberculin doses, which showed itself regularly about six hours after a dose, lasted six to twelve hours, and left her feeling brighter than before.

GENERAL SUMMARY.

The greatest difficulty in connection with the treatment arises from the impossibility of distinguishing in a given case whether the untoward symptoms are a result of an overdose or an accident of the case. In no one of the four cases was treatment completed without some discomfort to the patient. The principal untoward symptoms experienced were lassitude, weakness, loss of appetite, general sense of an impending illness, pain in the limbs. These symptoms where present reached their acme at from four to twelve hours after the injection. In two cases the untoward symptoms did not entirely disappear in the interval between treatments. In two cases they cleared up within a few hours.

No reaction of an alarming character, clearly connected with the treatment, was experienced. Two cases gained in strength and spirits during the treatment. Two cases lost decidedly in both. All four cases lost weight. No definite change in the physical signs was demonstrable at the end of treatment. The injections into the thigh caused much less pain at the time than those into the loins. The injections into the thigh, however, caused much greater subsequent lameness.

Reports of Societies.

HARVARD MEDICAL ALUMNI ASSOCIATION.

SEVENTH ANNUAL MEETING, JUNE 29, 1897.

THE PRESIDENT'S ADDRESS.

FELLOW-MEMBERS OF THE HARVARD MEDICAL ALUMNI ASSOCIATION, GENTLEMEN:—We have reached the age of seven years; and, although from the earliest times there has always been held to be something mystic about that number, there is nothing to show that we are any the worse or that we even feel queer for indulging in it.

For details as to the present status of the Association, I refer you to the last Bulletin, No. 10, which is in the hands of all, and will not detain you by repetition or elaboration. Some facts not therein contained or occurring since its publication it is my function to refer to.

By the death of Doctor, the chevalier, O. Robitaille, of Quebec, the Association loses one of its most distinguished members and one of the oldest graduates of the Medical School. He was born in December, 1811, in Quebec, took his medical degree at the Harvard Medical School in 1838, and died in November, 1896. He practised his profession in Quebec for nearly fifty years. He was a member of the city council, mayor of the city of Quebec, and a founder and governor of the two most important financial institutions of the province. His son, a practising physician in Quebec,

writes, "He spoke to me very often of his Alma Mater, Harvard."

An Alumnus in Iowa writes to your Treasurer in answer to a request for personal information and for attention to annual dues: "I enclose your note with post-office order. This note suggests several questions. How old am I? Seventy-seven last Friday. Not dead. Not much sign of old age about me except my white old head. I rode twenty miles in the country to-day without fatigue. Not an ache or a pain about me. Never drank any liquor, never had a chew of tobacco. Was I too poor to send the money due? By no means. Why have I neglected it? Damfino. Please accept this as my excuse."

An Alumnus in a distant town, who has been unable to practise his profession for some years on account of illness, finding it necessary to withdraw from the Association, writes: "I love the old spot Harvard and all of the associations. I may never see her again; but, when on my bed, I frequently think of and cherish the old names and friendships." Those who hold that graduates of the professional schools form no ties and have no sentiment for or interest in Harvard, and are not to be trusted with a vote for the members of the Board of Overseers, should talk with some of these Alumni. By vote of your council the tie which binds your sick brother to Harvard will not be severed.

The class graduating in 1893 has this year set the excellent example of having a class dinner, which it is proposed to make periodical. To judge from the dinner programme prepared for this festivity, neither the school training nor the subsequent stern realities of active life have been able to rob these devotees of an arduous profession of a capacity for relaxation.

The conception of such class reunions is a virtuous and praiseworthy one. May they increase and multiply, bringing forth much fruit in due season, and never forgetting the veneration due to the Faculty and to the School!

Since the last Catalogue, Bulletin No. 10, was issued in February, eight members have died, among these Dr. B. E. Cotting, of Roxbury, an honorary member by election, and an ex-president of the Massachusetts Medical Society. He died in May, at the age of eighty-five. The others were Dr. H. Blanchard, an old practitioner in Dorchester; G. W. Burdett, of Clinton; C. W. Cooper, of Northampton; J. W. Cushing, of Brookline; A. H. Nickerson, of Central Falls, R. I.; J. P. Walker, of Manchester, N. H.; and F. W. Whittemore, of Cambridge.

Since the last annual meeting seventy enrolment cards have been received by the Treasurer, ten of these coming from members of the Class of 1897.

There are seven new life-members since the first of last May. The list of life-members now numbers forty-four. I would again emphasize the desirability of this form of membership, especially for those who anticipate length of years, and who would escape the annoyance or inconvenience of remitting the small annual due. The Treasurer continues to suffer from the forgetfulness of some and the negligence of others, who, in remitting, omit to sign their names to the card which is sent them, and therefore cannot be credited. It seems necessary to remind the Association that the annual due is not used to defray the expenses of the annual dinner, which some attend, and others, on account of distance or more pressing duties, cannot enjoy,

but is used for the expenses of the Bulletins, which are sent to all, for such lectures as are occasionally given by invitation of the Association, and for other general purposes.

Since our last annual meeting four interesting lectures were given, by your invitation, by Mr. R. de C. Ward, Instructor in Climatology in Harvard University, on "Climatology and its Relations to Medicine." Arrangements have been made for a short series of lectures in the autumn by Dr. David Hunt, on the "History of Medicine."

The Council have had and still have under consideration several suggestions for the employment of surplus funds for the honor of the Association and the profit of the School, the support of an Alumni Association Scholarship being one.

There are three subjects in connection with medicine and medical education which are evidently forcing themselves more and more upon the attention of those whom they concern. Of these subjects you are likely to hear something from those who follow me in speaking to you, and you are likely to hear more from year to year. First, there is the absolute necessity of increased endowments for medical schools, — a necessity arising mainly from the large number of instructors and the increasing laboratory work. It is now recognized that the best clinical instruction is given to small classes. This means more teachers. In regard to laboratory work this is still more true; and laboratory teaching is costly teaching. The recognition of this necessity for endowments is exhibited in the eagerness of the old independent schools to ally themselves with organized universities. The latest instance of this was the attempt to unite the Bellevue Hospital Medical College with the Medical Department of the University of the City of New York. — an attempt apparently frustrated by the difficulty of fusing two such long names and two such large Faculties. It is said that the Bellevue School once before made advances to Princeton. The desire for a university alliance undoubtedly exists, and its value is illustrated. Endowments do not go so readily to schools managed as independent business enterprises for the welfare of the individual teachers.

The second subject is the consolidation of separate schools in the universities. This in a measure follows from the first, though the time may not yet be ripe for its application to the schools related to medicine, — the veterinary and the dental. If there must be increased endowments for more instructors, for larger and for more laboratories, there must also be a minimum of reduplication and of repetition.

The third subject is not entirely dissociated from the other two, and is certainly not the least pressing or important of the three. I refer to the constantly increasing disproportion between the immense development of the medical sciences, of the requirements of medical practice, and the ability or capacity of the individual, however favored by our enlarged facilities, to grasp these. Medical science is expanding by geometrical progression, and the possibilities of the individual who seeks to follow it by an arithmetical progression.

We have hardly finished congratulating ourselves upon the establishment of a four years' course. But the earnest teacher already finds that the earnest student of to-day with his four years bears a less, one might say a much less, favorable relation to the sum total of medical knowledge and requirements than did

the three years' student of twenty years ago or the two years' student of forty years ago to the knowledge of those periods. Art is getting longer and longer at a terrible pace; and time is really proportionately getting shorter and shorter in an almost discouraging fashion. This makes itself felt, not only in the schools, but in the sciences and in the practice of medicine. In the Congress of American Physicians and Surgeons there are fourteen societies, all founded within the last thirty-three years, and all but two within the last twenty-two years. More than ninety titles of papers were sent to the Section of Medicine alone of the American Medical Association at its annual meeting this year.

New medical periodicals are starting, and the best of the old are crowded with papers seeking publication. All the work done is not good work, as in other fields; but all is not bad, and the amount which has to be reckoned with is enormous. A new American *Journal of Experimental Medicine* was started scarcely more than a year ago. Already it is so unequal to the demands upon its pages that a new American journal is projected devoted to physiology alone.

For the student who is brought face to face with this state of things in his tender medical years something more must be done, and done soon. His student life cannot be again lengthened immediately, and there must be a limit. There must be a sharper line drawn between the absolutely essential and the unessential for a medical degree, a further development of graduate or post-graduate work, perhaps the establishment of a higher degree for those with larger aspirations and more waiting power, — for the medical scholars.

I scarcely more than mention these three problems which seem to me to claim serious study, and the last, at least, prompt action. I will not detain you to say all that I have in mind, for we are fortunate in having those with us who are eminently fit to discuss them.

I have had the honor of presiding over your Association for three years, and my presidential life has reached its constitutional limit. I desire to thank you for the confidence you have shown me, and to express my regrets if at any time either directly or indirectly I have been to any of you unwittingly a source of sorrow. I shall leave office with less reluctance realizing that you could not be better represented than by the successor whom I shall later have the pleasure of presenting to you.

(The report of the Committee on the Medical School, presented by Dr. S. W. Driver, of Cambridge, will be published later.)
